9. **PURULENT PELVIC INFLAMMATION.** "The patient complains of severe pain in the lower abdomen and in the pelvis, which often radiates down the thighs; there is a rise in temperature; the pulse is rapid and weak; and there is loss of appetite, great prostration, and often repeated chills. The rectum and the bladder may become irritable and cause painful urination and defecation. The abdomen is not distended as in peritonitis and there is no tendency to nausea or vomiting. *Diagnosis:* As a rule the patient complains of pelvic pain and tenderness during the examination. The mass formed by the purulent accumulation is irregular in shape, more or less diffused, and immovably fixed in the pelvis. It may be soft and boggy to the touch or it may be so completely surrounded by inflammatory exudate that it conveys a hard resisting sensation to the examining finger. As a rule, fluctuation cannot be elicited; but in large abscesses this sign is easily determined and the examiner has but little, if any, difficulty in recognizing the presence of pus. The *treatment* consists in evacuating the abscess without delay and establishing free drainage. Laparotomy should be performed, and a thorough investigation of the condition made; if the uterine appendages are found to be normal, the abdomen can be closed at once and the abscess opened and drained through the vagina. (From Ash-ton's *Gynecology*).

10. **COEXISTING UTERINE FIBROIDS AND PREGNANCY.** *Diagnosis:* "In many cases, the presence of tumors may have been recognized before impregnation. It will be easy to make out one or more hard masses connected with the uterus. If tumor is low down, it will be felt *per vaginam*, distinct from the presenting part. An ovarian dermoid will give much the same feel through the vagina, but it will not be so firm, nor so closely connected with the uterus, unless it is adherent. The differential diagnosis between the two conditions is of little importance, as the treatment of both conditions is the same. *Prognosis:* During pregnancy, if the tumor is large, pressure symptoms will supervene, and these may become so bad that an operation will be necessary; but, in many cases, the pregnancy will run an ordinary course. It is during labor that the most risk is incurred. If the tumor is low down, and cannot be pushed up, the condition is a serious one, and probably will necessitate an abdominal operation; but if it is high up, unless it be a large one, it may not have much influence upon the labor. *Treatment:* During pregnancy, a subperitoneal, or even an interstitial, fibroid may be removed without interfering with the pregnancy, but this is not advisable, unless there are indications calling for operations, such as pressure symptoms, or twisting of the pedicle in a subperitoneal tumor. To remove a tumor during pregnancy, because it is feared it will obstruct during labor, is a mistake. Even when the tumor is low down, it is often drawn up out of the way as pregnancy advances, so that, at full time, it no longer forms an obstruction. Another objection against operating during pregnancy, unless absolutely forced to do so, is that the uterus may expel its contents, when the child will certainly be sacrificed, if it has not reached a viable age. Even if it has reached that age, its chances of surviving are not nearly so good as at full time. To the mother the risk of operation at full time should not be any greater than during the pregnancy, provided she is in as good a condition. When an operation is necessary, either during pregnancy or labor, where it is at all possible the tumor or tumors should be removed and the uterus left. With multiple tumors this will not be possible, and a hysterectomy will be necessary." (Jardine's *Delayed and Complicated Labor*.)

Gonorrheal Epididymitis Treated by Diathermy.—Canovas treated 73 cases of this affection in all stages and obtained cures in from 3 to 4 days and marked improvement in one day. Patients are able to walk about freely during the attack provided that a suspensory is worn.—*Archives Médicales Belges*.

Disturbances of Vision by Cerebral Lesions.—

At a meeting of the Royal Society of Medicine held in London on December 12, 1917, Lieut.-Col. Gordon Holmes gave an account of exhaustive researches carried on by him in hospitals in France on disturbances of vision by cerebral lesions. He summarized the results of this study as follows: (1) The upper half of each retina is represented in the dorsal and the lower in the ventral part of each visual area. (2) The center for macular or central vision lies in the most posterior part of the visual areas, probably on the margins and in the lateral surfaces of the occipital poles. (3) The center for vision subserved by the periphery of the retina is situated in the anterior portions of the visual areas, and the serial concentric zones of the retina from the macula to the periphery are probably represented in this order from behind forwards in the visual areas. (4) Those portions of the retina adjoining their vertical axes are probably represented in dorsal and ventral margins of the visual areas, while that in the neighborhood of the horizontal axes is projected on to the walls of the calcarine fissures. (5) Severe lesions of the visual cortex produce complete blindness in the corresponding portions of the visual fields, or, if incomplete, an amblyopic color vision being generally lost and white objects appearing indistinct, or only more potent stimuli, such as objects moved sharply, may excite sensations. (6) The defects of vision in the fields of the two eyes are always congruous and superimposable, provided no disease or injury of the peripheral visual apparatus exists. (7) Lesions of the lateral surfaces of the hemispheres, particularly of the posterior parietal regions, may cause certain disturbances of the higher visual perceptual functions with intact visual sensibility, as loss of visual orientation and localization in space, disturbed perception of depth and distance, visual attention loss, and visual agnosia.

The Effects of Tobacco.—In a paper read before the Association of Health Officers of Nova Scotia (Quarterly Bulletin of the Department of Public Health of Nova Scotia, January, 1918), Dr. Fraser Harris gives a résumé of the effects of tobacco upon the body, of which the following were the conclusions: (1) The substances in tobacco smoke which are injurious are probably oxidation products of nicotine and other alkaloids. (2) The smoking of tobacco is the more injurious the younger the person, hence young recruits suffer more readily from tobacco heart than older men. (3) The chewing of tobacco is much more injurious than the smoking of it, and ought to be discouraged. (4) Since what is injurious in tobacco smoke is absorbed more readily by inhaling than by smoking without inhaling, inhaling ought to be discouraged. (5) There is in some cases a marked idiosyncrasy toward tobacco in respect of the substances which raise the blood-pressure, cause irregularity of the heart, and give rise to gastric acidity. (6) Those who have this idiosyncrasy ought not to use tobacco at all. (7) Those who do not have this idiosyncrasy may use tobacco in moderation with impunity.

MANIFEST PULMONARY TUBERCULOSIS.*

By COLONEL G. E. BUSHNELL, U. S. A. (Retd.).

WASHINGTON, D. C.

WHILE numerous articles in the medical press are devoted to methods of detecting incipient tuberculosis, the study of the more advanced forms of pulmonary tuberculosis is, in comparison, much neglected. The textbooks, with their numerous subdivisions and wealth of detail, are confusing to the beginner, who is apt to feel at a loss when confronted by the varied signs of large tuberculous lesions. Yet the importance of skill in diagnosis of age and kind of lesions present in a given case is great for all who have to do with tuberculosis cases, for upon such diagnosis depends the prognosis. Prognosis is the first and last thing demanded of the physician by the patient's friends, and upon the prognosis which he gives he is judged. In military medicine a correct diagnosis and prognosis is perhaps peculiarly desirable, because the conditions of military service frequently make necessary the transportation of tuberculous patients, sometimes over great distances. It is important, for reasons of humanity and for the credit of the medical officer and of the service, that he distinguish transportable from non-transportable cases. Too often it seems to be considered that, a case once labeled as tuberculous, all of the usual contraindications as to travel are removed and that a moribund patient may properly be sent on long journeys to seek, forsooth, the advantages of a change of climate. Medical officers should be held strictly responsible for the exercise of an enlightened judgment as to cases which may or may not be evacuated from their hospitals, not only as respects the obvious indication that dying men should be allowed to pass their last days in peace, but also the retention for proper periods of patients with exacerbations or with history of recent hemoptysis. In view of the above considerations it has seemed to the writer expedient to attempt a brief discussion of some of the salient points in the diagnosis of the manifest pulmonary lesion, with a view to indicate simple methods of reaching an approximate diagnosis and prognosis of the disease. The effort has been made to simplify the subject by the omission of all but the most important points, in the hope of furnishing clues for threading the maze of signs and symptoms of the advanced cases. As in all attempts at simplification, the danger is run of omitting too much—of making unguarded statements which may be all too successfully at-

tacked. It seems best, however, to run this risk rather than to incur the other risk of confusing the presentation of the subject, by guarding the statements made so carefully that the rules involved are lost sight of in the exceptions. No one can be more conscious than the writer of the difficulties of such an undertaking, and he offers this contribution in the hope that its shortcomings will be viewed with charity.

In order to assist the inexperienced, after a discussion of the various types of the disease, paragraphs have been added which indicate by questions the points which should be borne especially in mind in the study of the tuberculous lesion.

Fibrosis.—When tuberculous infection first takes place the cells of the body begin to receive a pabulum through the blood which is changed in quality; it has a tuberculous taint; the products of the tubercle bacillus and the albuminous constituents of the blood which have come in contact with these products and have been changed thereby afford a new nutritive problem for the tissue cells. They must hereafter obtain their nutrition from materials of an altered quality—they must learn to digest tuberculized albumen. Hence a change must take place in the nature of the ferments which are to convert the nutritive substances furnished by the blood into other substances adapted for the special needs of the cells in question. This change in the functional activities of the cells begins at once. Grüner and Hamburger think that a change in the reactivity of the body can be demonstrated to occur within six days after infection, but the initial changes are only a beginning. The process requires at least three months before it can be said to furnish a good measure of protection, and years elapse before the body has attained the power to digest tuberculized albumen or, if you please, to furnish tuberculocidal or bacteriocidal ferments, to the fullest extent of which it is capable. Immunity, then, shows itself in the ability to furnish ferments capable of attacking the tubercle bacillus and its products.

Looking at the process from another standpoint, we may say that immunity manifests itself in the ability of the cells to maintain their existence and to proliferate in the presence of the poisons of the tubercle bacillus. The well-nourished, vigorous cells will naturally gain such power more quickly and to a greater extent than those less healthy. The stronger and better nourished the individual, the greater his chance to acquire a durable immunity, provided that the initial dose of poison has not been too large. Excessive doses of toxic substances

or defective nutrition of the cell defeat the effort to acquire resistance. If the two unfavorable factors are combined, the result of the infection is disaster, immunity is not acquired, and the initial tuberculosis leads speedily to death. We may judge, then, of the degree of immunity by the success with which tuberculous lesions are isolated through the formation of a capsule of connective tissue which prevents their further growth. One disadvantage is, however, apparent in this isolating process, which is that the poisons of the focus are accumulated instead of being dispersed. A point may be reached beyond which the concentration of the poisons of the focus cannot be endured by the most vigorous cell, the cells die, small foci coalesce into a single large focus, and a cavity may result. Even yet there is an opportunity for the defense to rally, the cavity becomes surrounded by a thick wall of fibrous tissue, the more readily because the caseous tissue has dropped out and no longer poisons its environment, and the former lesion may first be discovered at autopsy after many years of immunity to tuberculosis infection.

This is the explanation of the hard saying that cavitation is a sign of immunity—immunity shows itself by the isolation of the focus even though such isolation leads to the death of the cells most closely involved. We see, then, in the most chronic cases, few and large foci sharply circumscribed and isolated, instead of the many and smaller foci surrounded by little or no new-formed connective tissue which characterize cases of less resistance. The process of isolation of the tuberculous focus being favored by relative rest of the part, large foci or cavities are typical of lesions of the upper part of the upper lobe, and are succeeded by smaller lesions as the disease progresses downward to parts of greater motion. Though the initial efforts to resist the spread of the disease may fail, the cells of the resistant organism still retain the power to proliferate in the presence of the toxic substances of the tuberculosis, the result of which, continued during many years, is the formation of great beams of connective tissue about the upper lesions. By the time that death finally ends the long struggle, the upper lobe, even the entire lung, may have become converted into a fibrous sponge, contracted sometimes by the drawing together of the fibrous threads into a small gristly mass of bronchi blood vessels and fibrous trabeculae which bears little resemblance to the normal lung either in size or in structure.

From the foregoing we draw two conclusions: first, the presence of abundant fibrous tissue is a sign of an old lesion; second, it is also a sign of relatively high immunity. From the physical properties of fibrous tissue, its relative non-vascularity, its contractility, and from its density as compared with normal pulmonary tissue we would expect that the lesion would be dry, that the tissues would be indurated, and that breath sounds would be conducted with increased distinctness. Fibrous lesions are in fact characterized by diminution or absence of râles, by well-marked dullness on percussion, by distinctness of transmission of the voice and, above all, by a sharpened inspiration and a prolonged as well as sharpened expiration.

The defense exerted by fibroid encapsulation is

often loosely spoken of as an absolute mechanical defense, as if the wall of fibrous tissue were really impenetrable for the tubercle bacilli. That this is not true is shown by facts such as the following: first, in well-marked cachexiae, as of cancer, reactivation of ancient tuberculous foci sometimes occurs; minute invasions of new-formed tubercles are found on close examination to have proceeded from hard contracted fibrous glands at the hilus or elsewhere in the deep lung, without evidence of active tuberculosis in other parts of the body; second, at autopsy we often find evidences of the invasion of fibrous structures by tubercles as part of the miliary extensions characteristic of the pre-agonal stage of the disease, perhaps as a row of minute tubercles like a string of pearls, threaded through the midst of a massive beam of fibrous tissue. The connective tissue wall is a protection, but not an absolute one, against further dissemination. Only the ferments produced by the immune cell can truly inhibit the growth and extension of the tubercle bacilli. Fibrous tissue thus invaded is no longer a dry tissue. But, with this exception, it is correct to say that in general the fibrous lesion is a dry lesion.

Caseation.—The effect of the presence of caseous foci is to produce a wet lesion. As will be understood from the foregoing, a caseous mass, even if surrounded by dense fibrous tissue, may still soften and liquify. We may have numerous caseous areas embedded in connective tissue, some of which are dry and apparently stationary, while others are in the process of breaking down. In general, however, the presence of numerous caseated areas discourages the formation of fibrous tissue. Where fibrosis predominates, the lesion is called fibrocaseous. Where tubercle is abundant, it is called caseofibrous. Thus, it will be seen, the presence or absence of moisture determines in a rough way the amount of caseous tissue present, the absence of moisture usually establishing the fact that there are at least no softening tubercle connected as open lesions with the air tubes of the part, while the presence of abundant moisture leads us to conclude with some degree of probability that the reverse is true.

Breath Sounds.—The bronchovesicular breathing in the chronic case may be said to be a sign of the presence of fibrous induration. It is also characteristic of the dry lesion. Dryness greatly favors the conduction of the bronchial sounds to the periphery. A wet tube may give not bronchovesicular* but rough breathing, or the breath sounds, at least in feeble or moderate respiration, may be indistinguishable from the normal, even though considerable induration be present in a fibrocaseous lesion. In massive caseation the tissues have lost their elasticity and, in so far as they are caseated, do not expand at all in inspiration. Ordinary breath sounds are absent in such cases or are present enfeebled in less complete caseations. Ordinarily what is heard is a weak and distant bronchial breathing, conducted from the deep bronchi and mingled with the coarse râles characteristic of these tubes.

*For the sake of brevity the term "bronchovesicular" is used to designate a change in breath sounds which consists in increased harshness or "sharpness" of inspiration and expiration, with prolongation of the latter.

The observer should, therefore, be on his guard not to draw necessarily a favorable conclusion from the absence of small or medium-sized râles when the patient's condition is bad. In gangrene, breath sounds are lost over the affected area. The same is true of plugging of the bronchi which may be temporary or permanent, the result in the latter case being ultimately caseation as a rule.

Râles.—Râles are divided into typical pneumonic râles, the crepitant and subcrepitant, and indeterminate râles, the latter including all râles not characteristic of acute pneumonic inflammation. Indeterminate râles may profitably be subdivided into typical and atypical râles. The typical indeterminate râle is moist, viscid, small, or medium in size (but always larger than the true subcrepitant râle), is heard during inspiration, bursts near the ear, and may occur in showers. It is formed in small bronchi, plentifully supplied with exudate as the result of inflammatory reaction to neighboring tubercle. Its presence is therefore a sign on the one hand of the existence of an active superficial tuberculous lesion, and on the other hand of the fact that there is no massive caseation, the tubercles are still discrete, and the process, therefore, either recent or of only moderate acuity. As the crepitant and subcrepitant râles are signs of acute inflammatory reaction, so the typical indeterminate râle is a sign of chronic inflammatory reaction; and, further, just as crepitant and subcrepitant râles disappear when exudate fills the alveoli, so does the small, moist, indeterminate râle disappear when bronchi become occluded or extensive caseation has developed.

The disappearance of small, moist râles in a given region of the lung with advanced lesions is therefore of as much significance as their presence. Localized persistent and numerous typical indeterminate râles constitute the best evidence of the existence of chronic inflammation in lesions containing discrete tubercles and furnish a means of determining the location of deposition of tubercle in fibrocaceous lesions. The atypical indeterminate râle is found in tubes which contain varying and usually relatively small amounts of fluid. Hence they have no fixed characteristics as respects size and time of occurrence in respiration. As a rule, in tuberculosis the atypical indeterminate râle is the râle of the large bronchi, but they are found towards the close of the early stage of miliary tuberculosis and in deep peribronchial tuberculosis. When they are disseminated over the entire lung, they are usually a sign of nontuberculous disease—heart disease, pulmonary edema, asthma, bronchitis, or pulmonary excretion ("gouty bronchitis").

In examining a large lesion it should be remembered that, except in the most acute forms, it is altogether probable that the greater part of the lesion will not be undergoing a typical inflammation at the time of examination. The problem will be to determine the regions where there is true activity and to distinguish them from other regions in which the process has burnt itself out, where, perhaps, râles come from small cavities interspersed in massive fibrous tissue or where fibrous tissue alone remains and transmits occasional râles from the bronchi beneath it. To accomplish this it is necessary to study carefully the characteristics of

the various râles which may be heard. Râles bear no necessary relation to sputum; indeed sputum is not a necessary concomitant of the tuberculous process—rather is it a complication, the evidence of irritation of neighboring bronchi. In some cases of extensive and active tuberculous disease there is practically no expectoration.

The degree of viscosity of the bronchial moisture is an important datum in the study of the chronic lesion. In fibrosis there is usually an old circumscribed lesion of the upper parts of the lung, a cavity or at least dilated or otherwise damaged tubes from which exudes more or less mucus, mingled usually with pus. Hence cough and expectoration are present as a rule in cases of fibrosis. When the fibrosis is the preponderating condition, the râles will be confined to the larger tubes and the mucus will be viscid and raised with difficulty, except so far as it may be diluted with the pus from pyogenic membranes. The coarseness of the râles reveals their origin. If small or medium râles are detected, the lesion probably contains softening tubercle and the prognosis as to prolongation of life is less good. The degree of viscosity and the abundance of the râles give some idea as to the relative acuity of the process, which is the more acute the less viscid within limits and the more numerous the râles. Least viscid of all the râles is the so-called serous râle. These are heard rarely in the chronic lesion under conditions which are little understood. The effect is as if the lesion had been flooded with a non-viscid fluid through which air bubbles. The râles are very numerous, burst without the characteristic delay of the mucous râle, as if, in other words, the rupture of the bubble were not attended by resistance, and have a peculiar, soft, breezy quality which cannot be described. This phenomenon is generally evanescent and is not inconsistent with a considerable prolongation of life.

Râles constitute the auscultatory evidence of inflammatory reaction to the poisons of tubercle. They are the best evidence that the lesion is resisting its foes. Râles are absent in the obsolete or arrested lesion—the body does not need to fight. They are present in the stage of reaction—the body is fighting—whether successfully or not is to be determined in part by the number and quality of the râles, in part by other considerations which will be taken up in the following section. They may be absent again when the body can no longer fight—when the power to react has been lost. Nothing could be more erroneous than to draw favorable conclusions from the diminution or the disappearance of râles in the very advanced case.

Symptoms.—As has been stated, the number and degree of viscosity of the râles justify conclusions as to the acuteness of the tuberculous process, many râles of slight viscosity denoting a process which is not progressing favorably, in which the lesions are breaking down with more or less rapidity. But conditions may be equally or more unfavorable when râles have become more viscid and scanty or finally disappear entirely. For the determination of such a case recourse must be had to the symptoms—it is very important to determine whether the disappearance of râles is a sign of good or evil omen. If the patient is gaining weight, if he feels stronger, if fever is abating or absent, if expecto-

ration of mucopus from cavities is lessening, the sign is a favorable one. If, on the other hand, the patient continues to lose weight, if cough and expectoration do not diminish, if fever continues and especially if it becomes more persistent and the patient's strength grows less, the absence of râles is to be interpreted as evidence that the reactive powers are beginning to wane. The condition is naturally only finally determined after continued observation.

Topical Diagnosis.—We cannot get a correct idea of the tuberculosis of the civilized man unless we think of it as a process which develops in the partially immune subject. Immunity against tuberculosis is produced successfully in the majority of the members of civilized races, so successfully that in fully 70 per cent. the disease is never recognized clinically, and in the remaining 30 per cent almost all the cases of the manifest disease present themselves under a form very different from that which characterizes truly primary tuberculosis. Manifest tuberculosis is due to a temporary or permanent, complete or partial loss of immunity. The forms in which it appears differ according to the degree of immunity which has been present, but usually there is evidence of a considerable resistance during the early phases of the disease. In the highly immune the manifestations of tuberculosis are the less apparent the more perfect the immunity; hence the failure to recognize the fact that tuberculosis is or has been present at all. However, the *x*-ray and the comparatively coarse tuberculin test, both subcutaneous and by the von Pirquet method, give positive results so frequently that the most reasonable hypothesis is that the immunity of the untested or negatively reacting minority is also due to tuberculous infection.

Normal Apex.—Breath sounds and percussion-note normal for location. Krönig's isthmus broad and equal on both sides. Apices resonant on Goldscheider percussion. Observation excludes well-marked chronic disease of upper part of upper lobe. *Does not exclude acute forms.* Examine for râles on ordinary breathing and with expiration and cough, above and below clavicle on both sides.

Apical Tuberculosis.—Observation shows that in the more resistant cases the first manifestation is in the apex. In the best cases the *x*-ray shows a single thickened line extending nearly vertically from the hilus, which ends in a network as the surface of the lung is approached, the lines of the network terminate at the pleural surface, as it were a stream which branches into a delta near its mouth. When the resistance has been less the lines from the hilus become multiple, the superficial network thicker and more complex, containing often one or more discrete fibrous or calcified tubercles. A lesion of this degree is rarely recognized during its activity. It results in contraction of the apex shown by a narrowing of Krönig's isthmus, an induration recognizable by accurate percussion, and by a slight change of breath sounds toward the broncho-vesicular quality. Progressively less resistant are the forms in which the initial foci coalesce into one or more large foci, which may become encapsulated or may lead to cavity. Usually by this time the process is no longer confined to the true apex and is more properly denominated tuberculosis of the upper lobe.

Whereas the first forms described are wholly benign and are not usually recognized as tuberculosis until light is thrown upon them by the *x*-ray, the latter forms are accessible to physical diagnosis and should be recognized by dullness, and by broncho-vesicular breathing with or without râles.

Apical lesions in the strict sense are of importance in diagnosis only as respects the decision as to whether a lesion is present at all. It is quite exceptional that a lesion in its acute stage is found in the apex which does not extend below the clavicle, though the possibility is of course admitted. The apical lesion being in continuity with the extension from the hilus, and being situated in lung which has little or no motion, is aborted in cases with reasonably good immunity. It then presents itself to the observer with the signs of a fibrous lesion. This fibrous lesion is often mistaken for a non-tuberculous collapse, or not detected at all. The nontuberculous collapse, being a simple atelectasis, is characterized by an enfeeblement or loss of breath sounds; the air does not pass freely into the lung, whereas in the fibrous lesion breathing is free and loud. The breath in both lesions may have the bronchovesicular quality, but this is more marked and louder in the fibrous lesion. From the fact that the apical lesion is usually found in an arrested state, it is often not recognized, and the later extensions lower down in the upper lobe are taken to be the first of the superficial lesions. The doctrine is held by many that the earliest incidence of tuberculosis is at a point lower down in the upper lobe than the apex, or is even at the upper edge of the lower lobe. The *x*-ray shows, however, that in the great majority of cases the apex is first of superficial parts to be invaded.

Upper Lobe Lesions.—Often the tuberculous lesion of the upper lobe has consisted in the deposition of a few tubercles which remain discrete, become fibrous or calcified or, if small, disappear entirely, and the existence of a lesion is to be determined solely by the signs which point to diffuse thickening of the connective tissue framework. If pneumonia occurs, the period of pneumonic inflammation being a self-limited one, the probability is great that lesions of the upper lobe will be first detected when they have reached a stage of chronic inflammation or of the induration or caseation which marks the terminal stage of the local process. As a matter of fact, it is quite rare that true subcrepitant or crepitant râles are found in this region. The lesion as it usually presents itself is a chronic lesion, characterized by a harsh inspiration and harsh and prolonged expiration, with or without indeterminate râles according to the activity of the process. Not rarely a well-marked lesion of the upper lobe is seen, which has run its course and becomes arrested without the knowledge of the patient and without detection by his physicians, in some cases notwithstanding numerous examinations. The writer recalls a clergyman coming for examination on account of hemoptysis, who had a typical paralytic thorax and extreme gastroptosis, who stated that because his appearance led to the suspicion of tuberculosis he had been frequently examined for that disease, in the large eastern city in which he dwelt, but always with negative results. Notwithstanding this history there was a well-

marked and good-sized lesion of the right upper lobe which was shown with great distinctness as an old and arrested condition by the *x*-ray. The history pointed back with clearness twenty years to the inception of the disease as a manifest process.

Less chronic and less indurated small lesions of the upper lobe are detected with greater difficulty. Percussion gives slight dullness on the affected side, with usually some increase in vocal resonance; the breath sounds are of the bronchovesicular type, but not necessarily markedly so. The measure of the degree of induration and contraction is sometimes better afforded by the narrowing or disappearance of Krönig's isthmus than by the classical signs over the lesion itself, which are often rendered indistinct by a compensatory emphysema of the neighboring lung.

The presence of an old lesion may only be shown by bronchovesicular breathing and a slight shortness or raised pitch of the percussion note, as shown by careful comparison with the other side. (Bronchovesicular breathing in the second interspace, right side near sternum, diminishing rapidly outward and downward, is normal. If the signs extend outward in the second and third interspace for more than a short distance, there is a lesion.) But it does not follow that a lesion of this kind is of clinical importance. There is as much difference in the severity of even arrested lesions as exists between a scorch of the skin and a burn of the third degree. It is one of the remarkable facts in physical diagnosis that slight changes in the fibrous framework, so slight as ordinarily to escape notice at autopsy, if they extend to the surface may be detected by auscultation and percussion.

In one case the *x*-ray shows a single line from the hilus, ending near the surface of the apex in small branches, the lesion dating back to a hemorrhage thirty-eight years ago without evidence of any signs or symptoms since that time. Several experts have independently determined the existence of an old lesion by physical diagnosis. The importance given to the determination of such obscure lesions rests upon the erroneous assumption that harshness of breathing and prolongation of expiration constitute signs of an incipient lesion. As has been said elsewhere, if the increased transmission of sounds from the bronchi is due to inflammatory engorgement, there is a frank lesion; usually these signs show a chronic condition. In estimating prognosis we should consider the intensity of the now obsolete process as carefully as its extent. There is a wide range from the lesion in which the pleura is glued fast to the ribs, breathing is harsh, dullness is marked, *x*-ray shows many strongly marked lines and one like that referred to above. The first type has some clinical importance; the second is to be neglected. It is therefore incorrect to fill wards with so-called suspicious cases in which the determination of the diagnosis is delayed from doubt as to the significance or importance of obscure signs, there being no reason why the diagnosis cannot be made at once. It is true, of course, that the possibility of a dissemination of tubercle, which has not yet given signs of its presence, introduces an element of uncertainty in *all* diagnoses, but the chance of such a dissemination in an obsolete lesion is much less than in a healthy part of the lung. It

is only justifiable to suspend the rendering of a diagnosis in cases in which the patient is much more ill than can be accounted for by the visible disease.

The Large Superficial Lesion.—Typically this lesion is made up of a cavity surrounded by abundant fibrous tissue above, below this a few large isolated tubercles, and still farther down numerous small tubercles. We find above well-marked dullness on percussion, cavernous breathing or very harsh bronchovesicular breathing, increased vocal fremitus and resonance with pectoriloquy over the cavity. Proceeding downward, an area is reached over which râles are finer, less viscid, and more abundant. Dullness less clearly made out or absent; a patchy crepitation, and voice sounds are less clearly transmitted. Still farther down the râles may be finer still, the dullness less clearly made out or absent; a batch of true subcrepitant or even crepitant râles may rarely indicate a beginning caseation. A lesion of this kind may be called a compound lesion. It represents at least three stages of development: first, the stage of cavitation in which the disease has burnt itself out; second, a stage of the development of large foci under conditions of fairly good resistance; third, a succeeding stage in which resistance has greatly lessened and the disease is beginning to have its own way. A process of this kind denotes a progress of years. The prognosis depends upon the kind and number of râles in the lower parts of the lesion and whether or not there is evidence there of circumscription of the process from the presence of fibrous tissue; in short, whether or not the breathing is of the bronchovesicular type characteristic of such tissue.

Is the breath bronchovesicular, with no râles, the changes in breath sounds being slight and well diffused, dullness being elicited with difficulty? Here we have an obsolete lesion with diffusion of fibrous induration of no marked degree. If the signs are well marked, we have more extensive fibrosis. The absence of râles, even after expiration and cough, shows that the lesion is arrested. Of course, the more marked and extensive the fibrous induration, the more severe has been the attack and the greater the likelihood that caseous masses are present in the lesion. The absence of râles shows them at least to be dry and well encapsulated. We speak of this lesion as a fibrous lesion, meaning, of course, a lesion the course of which is chiefly influenced by the fibrous component. If with the same signs small indeterminate râles are also present, the prognosis of the lesion is worse, because their presence makes it probable that there is softening tubercle. We infer as to the extent and importance of such foci by the abundance and wide distribution (or the reverse) of such râles. Numerous and well-distributed clusters of moist râles lead one to think of numerous disseminated caseous foci which are softening, whereas a few râles may proceed from a bronchus irritated by an insignificant tubercle. Proceeding downward, if the lesion is dry, do all the signs cease at the same line which is distinctly marked? If so, the lesion is arrested. This sign is obtainable with more distinctness in the case of well-marked fibrosis than in the more diffuse and indistinctly marked fibrosis due to sparse and small arrested

tuberculosis foci. In case of râles the lesion extends downward at least as far as râles are heard; dullness and breath changes may not be made out over its full extent. If râles extend below the other signs they will be rather small moist râles, which show a recent superficial extension of an acute kind. Patches of pneumonia may be found in such extensions, characterized by crepitant or sub-crepitant râles, but this is rare. The lesion in the case considered may extend by deposition of new tubercle below the physical signs, the foci not being apparent until inflammation has led to râles.

Study a lesion of this kind to determine the relative age of its parts and the topographical distribution of caseous and fibrous tissue. Is the lesion a simple one—that is, are the signs alike throughout, indicating contemporaneous involvement of all parts of it, or is there an older lesion above with well-marked bronchovesicular breathing and a relatively dry lung, while patches of râles below, with harsh breathing, indicate an active chronic lesion and much fibrous tissue or with nearly normal breath sounds show a wet lung with much softening tubercle; or, again, with normal breath sounds show the presence of an acute extension? Is the lesion above fibrous with preservation of much of the alveolar structures, or is the breathing cavernous, what remains of the lung being converted into airless fibrous tissue? Are the râles rather small or medium moist râles and numerous, indicating dense tubercle deposition, or are they coarse râles produced only in the cavity? Can more than one extension be made out—a fibro-caseous lesion below the cavity succeeded by an acute dissemination of numerous tubercles? Or, on the other hand, is the whole process arrested as to its downward progress, as proved by the fact that all signs terminate at the same level?

Peribronchial Extensions in the Same Lung.—In lesions of the upper lobe the force of inspiration being in the direction of the ribs, tuberculous lesions are most marked or in slight cases only existent near the surface of the lung. Extensions downward implicate especially the superficial portions of the lung and are conditioned by suction of lymph from parts of less to parts of greater expansibility. But in the lower chest the lateral expansion of the thorax has less influence upon the lymph supply than the movements of the diaphragm. The front of the invader is accordingly directed downward. There is this difference in the two situations, however, that the very mobile and expansile base is in too active motion to permit the establishment of tuberculous foci. Unless pleural adhesions prevent active motion, the base of the lungs generally remains free of tubercle, at all events until shortly before death. The tubercle invasion is checked in the bronchial tubes which run downward and outward and directly downward, but such checking tends to assemble the invaders, returning them to the hilus, whence they can act as reinforcements elsewhere. The bronchi which extend laterally through the lower lobe, since their lymph channels run nearly at right angles to the diaphragmatic suction, are particularly exposed. It is common to see an extension along such a bronchus which shows itself at autopsy as a series of bronchopneumonic foci grouped about the tube. Here we have what is really an atypical peri-

bronchial extension. During life our means of diagnosis do not permit the recognition of the fact, which is, however, worthy of note as respects the prognosis. We may put the facts in this way. Extensions in the lower lobe are more apt to involve the entire course of the bronchus, from the hilus to the periphery, than extensions higher up in the lung. What we judge of as superficial extensions of perhaps slight extent are here really the outward manifestations of a very considerable process, the greater part of which runs its course in the deep lung.

Lesions of the Other Lung.—All pulmonary tuberculosis is essentially bilateral, so far at least as the deep lung is concerned. The x-ray shows involvement of both deep paravertebral regions, but more marked as a rule upon one side than the other. On the side less involved the process may remain restricted to the deep lung, or in time it may in its turn reach the apex and develop superficial lesions of the upper lobe which do not differ in their pathology from those of the lung first attacked. As a rule lesions of the lung secondarily involved are larger and more acute than those of the side first affected. It is a very common error to overlook the initial superficial lesion and to consider the second as the first involvement, or, if the presence of a small lesion is discovered, to consider it secondary in point of time to the larger lesion. The distinction is made as follows: the older lesion will show obliteration or greater contraction of Krönig's isthmus, a harsher breathing, and a more prolonged expiration.

Although the first extension from the hilus is peribronchial, after the period of manifest tuberculosis is reached peribronchial extensions are almost always secondary to superficial and more or less circumscribed lesions.

When a tuberculous process has run its course and become arrested, the process having been sufficiently marked to arouse successfully all the defensive powers of the organism, the result is a certain local immunity. Tuberculosis will not develop anew at this place as readily as elsewhere in the lung. If, therefore, a patient presents evidences of constitutional impairment (fever, lassitude, purulent expectoration, etc.), and a superficial examination shows a completely dry lesion of, say, the right upper lobe, it will not do to ascribe the symptoms to this lesion—an arrested lesion has no symptoms. Especial care should be taken to examine the opposite side, in this case supposedly the left, for the slight evidences of peribronchial processes which are so readily overlooked by the careless observer. Failure to institute proper measures in season may lead to an intensification of the peribronchial process such that, when it finally forces itself upon the physician's attention, the case is quite hopeless so far as recovery is concerned; whereas, if taken in time, it might perhaps have become arrested.

Examine with especial care the character of the breathing of the upper lobe of the other side, comparing it frequently with a normal part of the lung. Do not commit the error of considering a tympanitic note over an acute lesion to be normal, the normal side to have dullness. The distinction is made by the pitch. The diseased side will have a higher

pitched, shorter percussion note. On the side with the broader Krönig's isthmus is there also a lesion? Is the bronchovesicular quality of the breath sounds less marked, showing a more recent extension? Are râles present showing activity? If a superficial lesion is not made out, does careful comparison of the breathing of this side with a normal part of the lung show a bronchovesicular quality to be present? Does it extend throughout the upper lobe? If so, there is a peribronchial extension. This may be purely lymphangitic, or, being of greater severity, it may still be arrested, in which case there will be no râles and the prognosis is good. If râles are present, they vary from very abundant to scanty. The prognosis is bad in proportion to the abundance and distinctness of these râles.

Do not expect to find, as a rule, râles which break near the ear; the early râles of peribronchial tuberculosis are indistinct and atypical. It is as if one were obtaining signs of a process which is evolving nearly out of reach. It is important to exclude a massive peribronchitis, limited to the deep lung, which sometimes occurs. The characteristic physical sign of this process, when well marked, is a limitation of the expansibility of the lobe involved, not to be explained by other factors (pleural adhesions), and a higher pitched percussion note on strong percussion as compared with the symmetrical point on the other side. The percussion stroke should be heavy, in order that it may set the entire side in vibration, the idea being to see whether the fundamental note of the lower thorax is altered by a loss of homogeneity through deep infiltration. A radiograph is of immense assistance in the determination of such cases.

The Bilateral Type of Peribronchial Tuberculosis.—We consider here only those forms of fibroid or cirrhotic change which can be ascribed to tuberculosis. The presence of tubercle bacilli in the sputum and the history of tuberculous disease are important data in the diagnosis.

In cases with high immunity in which the process at one time has been severe, the x-ray shows both lungs involved with long and heavy streaks radiating out from the hilus, following the normal course of the bronchi and blood vessels and representing these structures thickened by an enveloping fibroid induration. The two sides are not universally or equally involved, but on both the induration extends well into the lower lung. This condition may develop and become arrested without leading to conspicuous symptoms, the extensive fibrosis revealed by the x-ray being often greater than signs would have led one to anticipate. In other cases the shadows are massive and the course of the tubes and vessels is no longer apparent. The enormous formation of fibrous tissue speaks for a high original immunity, but at the same time an immunity which has been excessively stimulated; in other words, there has been a strong reaction to the presence of widely spread tubercle bacilli and bacillary poisons. The more massive the indurations the more likely therefore that they contain disseminated tubercles. Such tubercles may have become calcified or fibrous at the time of examination, so as probably no longer likely to be of harm, or they may be a source of great danger. The distinction is twofold: First, the presence or absence of râles;

second, the general condition of the patient as respects emaciation and fever. The râles are indeterminate, not very large nor very viscous. They may be disseminated irregularly over both sides; they may be irregular in their appearance, being heard, for example, over the back on both sides at one examination, again only or chiefly on the right; and still again only or chiefly on the left. No favorable deduction should be drawn from the diminution or disappearance of those râles unless such changes be shown to be permanent. This they almost never are.

The system has put forth enormous efforts in laying down the almost incredible amounts of fibrous tissue. Notwithstanding these efforts the râles show that the defense has been a failure, a secondary crop of tubercles has made an invasion, and this is really the beginning of the end which, manifesting itself usually as a miliary extension, is deferred more or less according to the patient's mode of life. The breathing in both types is harsh, with prolonged expiration. Dullness is distinctly present. The transmission of the voice is increased, but owing to the bilateral character of the affection gives little useful information in typical cases. In those cases in which extensive fibrosis has been superadded to an originally slight, well-encapsulated lesion there is no cough and expectoration. If a cavity of the upper lobe has not dried up the sputum is characteristic of that condition. Cough and purulent sputum in conjunction with râles, in cases in which no unhealed cavity exists, are too often an ominous sign.

Acute Peribronchial Tuberculosis.—There remain to be briefly described those cases in which there has been a sudden and extensive formation of tubercle about the bronchi. In the cases seen by the writer this has occurred on the heretofore healthy side, opposite an old and apparently nearly or quite healed lesion. The disease may develop without warning in persons who believe themselves quite well. In this dreadful type of peribronchial tuberculosis the masses of tubercle are grouped so thickly about the bronchi that the latter become inflamed. The peribronchial becomes bronchial tuberculosis—that is, the process progresses toward the lumen of the bronchus, in some places it perforates at an early date, and there is bacilli-laden sputum. Over long stretches the tubes are as yet only stiffened with inflammatory exudates and the mucosa is irritated and swollen. A reflex cough is excited, which is incessant and perfectly hopeless as to results. The only relief for the unfortunate patient is efficient doses of morphine, the effect of which, however, soon wears out. The spasms of cough generally terminate with vomiting, which is further favored by the large doses of morphine, and the patient is speedily worn out by the addition of inanition to his other troubles. The breathing in this class of cases is of the bronchovesicular type, perhaps harsher and louder than in less severe cases. Here, exceptionally, the breath sounds are conducted along the bronchus by an acute inflammatory instead of a fibrous induration.

Large Sluggish Lesions.—The large lesion which has been described with the cavity or the well-marked fibrous area above, succeeded by smaller cavities or by relatively small caseous foci imbedded

in a more or less abundant fibrous tissue, to be perhaps succeeded in its turn by a series of much smaller, more or less closely aggregated tubercles, is a condition which presents sharply drawn characters. It is typical in its development and is easily diagnosed, the physical signs are readily heard through the thin chest wall, and there is perhaps just a shade of dyspnea which results in a force of breathing well calculated to make the auscultatory signs distinct without conscious effort on the part of the subject. The most salient characteristic of a lesion of this class is its development according to law. There are individual differences, of course, of omission or of intercalation, but on the whole there is a typical course which is determined by two factors—the immunity of the individual on the one hand, and, on the other, the relative mobility of the part. Hence we expect cavities and fibrous tissue at the summit, followed by progressively smaller and more numerous lesions as the mobility of the lung increases downward and the lapses of immunity become more serious. The lesions might be compared to a mountain—craters extinct or active at the summit, farther down caves, and, still farther, stratified rock of various kinds. But there is the difference that, whereas in the mountain the age of the different levels increases downward, in the lung the lowest stratum of tuberculous tissue is the most recent—a topsy-turvy geology, as it were.

But there is another class of cases in which the diagnosis is not so easy. We distinguish two types. The first is obscure in its manifestations because the lesion consists essentially in a disseminated fibrosis, which from its nature does not give very sharply marked signs. The problem here is to determine by comparison with the other side whether or not the tissues have been impaired in resonance and have had their conductivity of sounds increased, with the further important question: Is there evidence of the presence of disseminated tubercle and, if so, are these foci in a condition of activity? The problems which such a case presents are not difficult of solution for one whose ear is trained to detect minute changes in breath sounds and percussion note, except so far as the decision as to amount of caseous tissue present is concerned. The difficulties of the inexperienced are due to two causes: first, expecting to elicit well-marked physical signs; second, giving morbid significance to normal topical variation in breath sounds.

But there is another class of cases with larger and older lesions in which, while they are still no doubt subject to law, the laws which govern are plainly quite different and less easily explained, and the lesion when interrogated stands mute, it may seem, to the uninitiated, or gives out information as to its nature but sparingly. Such a lesion is usually found in cases of long standing in which the patient has been under favorable conditions as respects food and rest, but has been slowly retrogressing. If one examines such a lesion, dullness is present nearly everywhere over the thorax, breath sounds are faint or inaudible over the greater part of one or both lungs, râles are atypical, found here and there, differing in number and distribution at succeeding examinations, and the conduction of the voice is rather diminished than increased. In short, the examiner may conclude his examination with

the feeling that there is undoubtedly a tuberculous lesion, but that the determining of its age, distribution and prognosis is a very different matter. In such a lesion the difficulties of diagnosis are largely due to the presence of extensive plastic pleural exudates which act in various ways to obscure the physical signs. Chronic tuberculous affection of the superficies of the lung are, as a rule, accompanied by a certain amount of plastic pleurisy. Pleurisy of this kind can only occur when the tuberculous involvement of the visceral pleura and underlying lung is slight and chronic. In other words, adhesions cannot form over large caseous foci. The beneficent effect of pleurisy in prolonging life is not always considered. In its absence the first good sized caseous tubercle that breaks down upon the surface of the lung will infallibly lead to pyopneumothorax. That this complication is comparatively rare is the best proof of the rôle of the pleural adhesion. We expect, then, more or less pleurisy to accompany every well-marked and large chronic lesion.

In cases with high immunity, in which lesions develop slowly and are well demarcated, the pleurisy is, as a rule, limited to the immediate vicinity of the lesion, leaving the lower lung free to expand in respiration and thus check the downward progress of the disease. In such cases we find that the basal parts of the lung furnish strong respiratory sounds, and the autopsy shows this portion of the lung to be free of manifest tubercles. But in cases of less immunity, especially in the lung secondarily involved, in which a disseminated extension has taken place, pleurisy may tie down the entire lung, even involving the diaphragmatic pleura. A lung thus affected operates under different laws. It is in a condition of enforced rest, is incapable of full expansion and, under ordinary conditions, does but little of the work of respiration. It therefore comes under the influence of the law that lesions forming under conditions of rest will be larger, more discrete, and more likely to break down into cavities. One sees rarely at autopsy a lung completely adherent everywhere through which are interspersed large caseous foci, such as are characteristic of the upper lobe lesion. Usually, however, the lesions have been laid down before the lung has become motionless, in which case they are small and numerous, and the question is: Will the effect of rest be helpful or harmful? The answer is, helpful if the dissemination is sparse, in which case the individual foci may become fibrous or calcified; harmful if the dissemination is dense, the stagnant poisons then tending to break down the healthy tissue between the tubercles, with the result that the lung melts down into a vast cavity if life is sufficiently prolonged.

In the majority of cases, however, the termination is neither fibrosis nor cavitation. The lesions, neither very sparse nor closely aggregated, pursue an extremely sluggish course, and the patient is generally carried off at last by some complication such as pneumonia, or his entire loss of immunity is shown by a final crop of miliary tubercles in the lungs or throughout all the viscera.

Even in these cases the signs of a former immunity may be shown by the difference in behavior of the two lungs. In one the tissues are drier,

there is a sharper respiration, there may be old cavities in the upper lobe, the lesion is more sharply demarcated below, the lung below the lesion may be free of morbid signs, and the respiration of the individual may be largely carried on by it; whereas, on the other side, the breathing is faint, often apparently normal, râles are indeterminate, rather large and few under ordinary breathing, sometimes developing showers after effective cough. The percussion note is dull everywhere, sometimes approaching flatness in the lower axilla. Flatness is, of course, a sign which should at once lead to the suspicion of the presence of effusion. But in the class of cases under consideration the percussion note is very dull, rather than flat. *Fremitus* is absent, but vocal resonance can still be obtained. This is known as Kuthy's dissociation phenomenon. The discoverer explains the absence of *fremitus* by the supposition that the voice cannot cause a commotion of the thoracic wall because the vibrations are checked in passing through the non-homogeneous stratum of the thick plastic adhesions, whereas the sound of the voice, having greater penetration, still reaches the ear.

In studying these difficult cases, determine first which lung has the older lesion. Often the patient knows only of the older lesion, believing his disease to be unilateral. Fibrosis and cavity above, succeeded below by well-marked bronchovesicular breathing throughout the lesion, the lower edge of which is sharply demarcated, the breathing at the base being free, and exaggerated or puerile in character, are favorable signs. The prognosis of this lesion depends, however, chiefly upon the number, density (abundance), and size of the râles following the cough. Usually the lesion is a wet lesion, approaching in its character that of the newer lesion of the opposite side. The more recent lesion is characterized usually by absence of cavity, or cavities when present will be recent, and by feeble respiration with inability to increase its force above a certain slight degree. Often the examiner will believe that the patient is making no effort to breathe until comparison with the other base shows powerful respiratory movements with correspondingly loud breath sounds there. Vocal resonance may be less loud than on the other side, but everywhere present. The presence or absence and the distribution of vocal *fremitus* furnish a clue as to the density and thickness of the plastic exudate of the pleura. The lesion is a wet lesion, the number, size, and density of the râles constituting the best guide to the condition as respects caseous foci. In general the prognosis as respects prolongation of life is better the more obscure the physical signs, and it is to be determined partly by the amount of fibrosis present, but chiefly by symptoms (fever, expectoration, emaciation, loss of strength, etc.) rather than by signs. Here, as in other advanced lesions, the observer should be on his guard against drawing favorable conclusions from the absence of signs of moisture if the patient's general condition is distinctly bad.

In studying these lesions Krönig's isthmus may not indicate the age of the lesion, being contracted on both sides. The older side may show a sharper breathing, a smaller lesion, a free base, perhaps a larger cavity. Are there extensive pleural adhe-

sions as shown by restricted breathing? Are vocal resonance and *fremitus* increased, showing the influence of the parenchymatous lesion, or diminished, showing an extensive plastic deposit in the pleura? What is the amount of fibrous tissue? Are there extensive areas with dullness and harsh breathing but without râles, or is the whole lung wet and the bronchovesicular quality absent or but slightly marked in the respiration? Do showers of râles on expiration and cough show that there is inflammatory reaction of softening tubercle, or are the râles few and coarse from cavities or irritated bronchi? The prognosis will probably be determined by the condition of the more recently involved side. Is the lung involved throughout or to a lower level than the other side? Bear in mind the effect of extensive pleural adhesions in restricting the breathing so that less information will be obtained from study of breath sounds. Percussion gives much useful information here. Distinguish the very dull note of plastic exudate from that of the more resonant parenchymatous lesion. Is the newer tubercle breaking down? Are there indications of a cavity of the lower lung? Do not forget to exclude empyema and localized pneumothorax. Consider carefully the patient's general condition and bring it into relation with the physical signs.

There is one class of cases apparently similar to those just described, which presents great difficulties in diagnosis and prognosis. It may be described as a lesion with all the evidences of advanced disease, dullness, changes in breath sounds, abundant moisture, etc., in which the patient's general health is good entirely out of proportion to the apparent gravity of the lung conditions. The writer has in mind one case in which the breathing of the right lung was greatly restricted and the lung was everywhere full of râles, in which there is rarely fever, the nutrition and appetite excellent and the patient so little conscious of ill health as to be desirous of accepting a commission in the Medical Reserve Corps. Here we have a case in which firm adhesions interfere with the play of the lung and lead to stagnation of the lymph, the moisture apparently being due in large measure to such stagnation rather than to the exudation of active inflammation. It is probable that the fluid in the lung of such cases is due in part to errors of metabolism, but this is a point which demands further study. The determination of such cases is made by the dissociation of signs and symptoms. The patient's condition appears desperate from physical signs, but the symptoms indicate a very tolerable, though, of course, precarious, state of health which may be enjoyed during some years. Here, as in all advanced cases, symptoms furnish the surest clue to the prognosis.

The Cavity.—Cavities result from the death and absorption of pulmonary tissue. They are divided into superficial and deep, open and closed cavities. Occasionally a cavity of the upper lobe is seen in which the entire interior of the lobe has been scooped out, leaving walls of air-bearing tissue. Such a cavity is difficult of diagnosis, especially as respects its extent, even a thin wall containing air-filled alveoli having an extraordinary effect in diminishing the conduction of sound. As a rule, however, the cavity, especially the large cavity, has de-

stroyed the superficial lung so that its external wall consists of little more than the two layers of the pleura glued together and firmly adherent to the ribs. From such a cavity sounds are conducted with startling distinctness. Most characteristic is the conduction of the voice and the whisper. Spoken words seem to be enunciated from the depths of the cavity; hence the term *pectoriloquy*. Whispering pectoriloquy is equally or more distinct in its peculiar reproduction of spoken words than is phonation. The râles produced vary greatly, according to the quantity of fluid present and the resonance of the cavity walls.

A very large cavity is always a more or less wet cavity. Small cavities are difficult of diagnosis. Occasionally a cavity is detected by the x-ray which gives no physical signs. Conversely, a cavity may be diagnosed by physical signs which is not shown on the radiograph. A closed cavity gives no certain physical signs. If full it is equivalent to an abscess. The presence of such a cavity may be suspected if its location and weight are such that it exercises a pull upon the pleura, in which case there is the characteristic hopelessly unproductive "pleural" reflex cough, which, once heard, will always be remembered. A deep cavity also presents some difficulties in diagnosis. The marked physical signs due to the resonance of the walls of the superficial cavity are absent. Often the only sign is a respiration in which inspiration is almost inaudible, expiration being very prolonged and deep-pitched. A variety of the deep cavity is the serpiginous cavity, which appears at autopsy as a narrow sinuous tube extending sometimes far down into the lung, as if the process of its formation had consisted in a progressive melting away of the bottom of the sac. Its importance lies chiefly in the prognosis of hemorrhage. When in its downward course a cavity of this kind encounters a blood vessel, hemorrhage is likely to ensue, which is raised with difficulty, the greater part of the effused blood infiltrating the surrounding lung. The fact that hemorrhage may appear to be slight or that it ceases altogether is of no importance if the patient's face becomes cyanosed. This is a fatal sign, evidence of the extensive infiltrations of the deep lung with blood which the autopsy will speedily reveal.

If the breathing is characteristic of cavity, we have to determine the size and position of the cavity and the condition of the surrounding tissue. Are the sounds from the cavity very marked, reaching the ear with the greatest distinctness? Is the percussion note tympanitic or very resonant? We infer, then, that the cavity is superficial and the pleura adherent. Passing in all directions from the point where the sounds are most distinct, the patient counting vocally or in a whisper, note where the pectoriloquy, though still plainly heard, becomes less loud. We are now over lung tissue, but it is not always easy to determine whether the cavity still extends behind that tissue, the difference in sound being merely due to the interposition of a thicker wall, or whether the sounds are reflected downward into uninvaded territory. However, the important question is: What is the condition of the surrounding tissues or, what amounts to nearly the same thing, what is the nature of the cavity? Is it progressing or stationary? The walls of the

cavity may be of smooth and firm fibrous tissue throughout, or of sloughing masses of caseous material, interspersed among thickly studded softening yellow tubercles of small size; or there may be intermediate cases in which the tubercle persists in only a portion of the wall, usually the floor. The first type is characterized by the distinctness and metallic quality of breath sounds and râles, often by the scantiness of its contents (shown by the fact that râles are only elicited at the base of the cavity) and by their frequently tenacious character, the blast of strong respiratory movements of air producing what are plainly waves ruffling the surface of a mucilaginous pool, as it were.

When the walls, on the other hand, are soft and crumbling, the sonority of the acoustic phenomena is much diminished. Pectoriloquy is still present, but one fails to get the impression of a resounding cavity. On expiration and cough the sides of the cavity are brought into apposition. Their separation in the following inspiration is sometimes manifested by a whiff and by a sound resembling numerous simultaneous small râles. The contents of the cavity are usually much more abundant and râles of varying quality are obtained at a higher level. If the breaking down is rapid and the fluid largely pus, râles are not necessarily conspicuous or peculiar. In some very advanced cases, however, there is an extraordinary viscosity of the greenish-yellow, often blood-stained, sputum, which has been ascribed to the presence of nucleinic acid. In such a case the sputum hangs in ropes in the patient's mouth, and he often attempts to extract it with his fingers after repeated failures to expel it in the usual way. In the cavity the same viscosity of its contents leads to the most remarkable variety of râles, snoring, bubbling, creaking râles, the sound of "new leather," simulations of friction rubs and the like, the diagnosis of which, if there is doubt, is speedily cleared up by the change effected by a coughing fit. The sputum varies with the nature of the cavity contents, mucous or mucopurulent, viscous, comparatively scanty and raised with difficulty in the first type, more abundant, more frankly purulent, easily raised in the second type, raised with some and expelled with more difficulty in the variety just described. If the cavity is not large we must ask ourselves the question: What is the character of the remaining solid structures? About the encapsulated cavities, which may be multiple, there are masses of fibrous tissue that are completely destitute of patent alveoli. In such cases no respiratory sounds are forthcoming from the surrounding parts, the indurated tissues of which transmit the cavity sounds with great distinctness. The condition of the air-bearing tissue in the neighborhood of the cavity is determinable by criteria already discussed. A bad combination as respects general prognosis and also in the present case the probability of extension of the cavity, is apparently normal low-pitched respiration, with an abundance of râles, and, worse yet, is such an abundance of râles as to render the breath sounds inaudible.

One variety of the cavity which sometimes escapes the unwary is one in which the lumen of the cavity is practically obliterated by a dislocated heart. Some change in the heart's position probably occurs in every case of at all extensive cavity,

the lung on the healthy side expanding to fill the vacancy and pushing the heart before it. In some cases the dislocation of the heart may be marked, the greater bulk of the heart being found to the right of the median line of the sternum, or in the left-sided cavity it may be tucked away well up toward the axilla. He who does not percuss out the heart and determine the location of the apex beat as a part of his study of lung conditions is doomed to an occasional unpleasant surprise. One more word on this subject. Do not ascribe any signs of failing heart or possibly venous obstruction to a kinking of the great vessels as the result of the heart's displacement. The heart can be swung in any direction within the thorax without leading to any diminution of caliber of these vessels through undue approximation of their walls, as dissections have convinced the writer.

Miliary Tuberculosis.—The term "miliary" relates merely, of course, to the size of the tubercles. A better name would be "disseminated hematogenous tuberculosis." The complete failure of immunity, which so often immediately precedes and is the cause of death in tuberculosis, is the signal for the development everywhere of tubercle, often minute and determinable only by the microscope, sometimes of a more chronic type and appearing as macroscopic yellow tubercles. It is incorrect to speak of death as occurring from miliary tuberculosis in such a condition. The term should be reserved for cases in which there is a large or a universal dissemination, often from an old and apparently insignificant focus, of minute tubercles which constitute the principle disease. Much study has been expended upon the causes of this condition, but the point upon which especial emphasis should be laid is that the initial condition which is the real cause of miliary tuberculosis is the complete failure of immunity, which allows collections of tubercle bacilli to be set free and to establish everywhere new colonies. Miliary tuberculosis as studied in the lungs gives at the outset no signs and symptoms. It is invisible to the x-ray. In physical examination of the chest, in a case in which the overwhelming of the vital forces is apparent, day after day no signs are obtained. At last distant and faint atypical indeterminate râles are to be made out. By this time there is a characteristic restraint of the breathing. The lung expands slightly and ineffectually and gives the impression on auscultation of a body which moves slightly amid wet surroundings. If life is prolonged until softening of the tubercle has taken place, the râles are more characteristic and nearer the ear, and the x-ray reveals a multitude of minute shadows.

Hematogenous disseminations of tubercle may be sparse or dense. Their characteristic feature is their irregularity of dissemination. Peribronchial tuberculosis is known at autopsy by the occurrence of "clover leaf" groupings of tubercle, which represent sections of bronchi and bronchioles filled with caseous material or with pus. When section at autopsy shows thickly set tubercles, in great part of the same size and equally placed, the condition is not miliary tuberculosis but the last stage of a bronchitis or bronchiolitis which is the termination of the most marked forms of peribronchial tuberculosis.

METHODS OF PREVENTION AND CONTROL OF DISEASE IN WAR INDUSTRIES.*

By J. W. SCHERESCHEWSKY, M.D.,

WASHINGTON, D. C.

ASSISTANT SURGEON GENERAL, U. S. PUBLIC HEALTH SERVICE.

THE present struggle has demonstrated in the most forcible way that the effective organization of industries is fundamental in the successful prosecution of modern war. Mere numbers avail but little against an enemy who has brought war industries to the highest pitch of efficiency, unless, in like fashion, war materials and the means to transport them be forthcoming to a hitherto unprecedented extent.

Success in this can be achieved only by maximum continuous production over the entire interval of the war. There is abundant evidence to show that the most important factor influencing production is keeping the workers continuously well. As the British Health of Munition Workers' Committee so cogently remarks, "Without health there is no energy; without energy there is no output."

As output will win this war, the vital necessity of maintaining the health of our industrial army at the highest possible level is self-evident. Unfortunately, as has been so ably shown by the preceding speakers, the conditions surrounding war industries are such that workers are intensively exposed to such health hazards as industrial poisons, high degrees of heat and humidity, defective conditions of illumination and ventilation, to dusts and fumes, to excessive muscular strain, to noise and vibration. In addition to these, there are the harmful effects of speeding up and over-fatigue caused by the endeavor to furnish supplies in the enormous amounts required.

Nor are the hazards of the work-place the only ones to which our industrial army is exposed. There are the defective sanitary conditions arising in the industrial community itself, which menace the health during the hours passed outside the workplace. While we have always had defective community conditions in the past, the extent of such conditions has considerably increased because of the great influx of workers to newly developed industrial centers.

A continuous state of health of the industrial army, therefore, can be secured only by the application of measures for the intelligent supervision and control of sanitary conditions in industrial plants, for the prevention of occupational diseases and poisonings, for the medical care and supervision of the working force, and for the elimination of defective sanitary conditions in industrial communities.

A forcible illustration of the necessity for such provisions is shown by the experience of Great Britain. Although the factory system of the British Empire is subject, in normal times, to many wise regulations for the safeguarding of industries, nevertheless, at the outbreak of the war, in the desire for maximum output, industries were speeded up without adequate supervision to the

*Read at a meeting of the New York Academy of Medicine, March 7, 1918.

breaking point; sanitary precautions ordinarily enforced were disregarded during the period of initial stress; long hours and long periods of overtime were worked. In addition to this, all volunteers, physically acceptable, were enlisted without regard to their ability as industrial workers. Many women were drafted into industry to replace men, thus exposing them to industrial hazards with which they were unfamiliar. These conditions so slowed up output that it became necessary for the British Government to supervise the industries from the health standpoint and to recall from the front workers who should never have been diverted, in the first place, from the service they were peculiarly able to give.

Prior to the entry of our Government into the war, the furnishing of munitions to the Allies had already stimulated exceedingly the extension in this country of the industries concerned, namely, the explosives and munitions industries, the textile, the metallurgical industries, the chemical and allied industries, the rubber, shipbuilding, and leather industries. The part now being played by our country in the war will still further greatly enlarge the previous activities. New plants for the production of war materials will spring up, like mushrooms, over night. It is to be expected that men will undertake production in government contracts who have had but little previous experience with the manufacture of the materials in question and the hazards to the health which may surround such manufacture.

Moreover, in view of the recent march of events in Europe and submarine activities, time seems a vital element in the successful military intervention of the American people. It, therefore, seems imperative, on the part of the Federal Government, if the European experience is to be avoided, to exercise such supervision and control of the sanitary conditions surrounding war industries and the health of the industrial army that the health requisite to maximum output will be insured. That the need for such federal supervision exists at the present time has been amply shown by the previous speakers by investigations already made in such industries by officers of the Public Health Service and by others.

Thus the explosives and munitions industries present the hazard of industrial poisoning by such coal-tar compounds as T. N. T. and tetryl, which already have caused, both in this country and abroad, numerous fatalities, and a much greater number of acute and chronic poisonings. Yet it is possible, by proper precautions, well-nigh to eliminate these causes of lowered efficiency and ill health.

Apart from the munitions and explosives industries, other industries essential to the successful prosecutions of the war each present their own specific health hazards. For instance, in the manufacture of airplanes, the solvent used in "doping" wing fabrics is often highly poisonous, so that its use may cause many cases of poisoning and death unless adequate precautions are taken.

The "nosing" of shells, the manufacture of shrapnel bullets, the loading of shrapnel shells will expose the workers to the dangers of lead

poisoning unless proper precautions are taken. Again, in the rubber industry, poisonous compounds are used which may readily result in serious poisoning unless protective measures are applied.

Besides the high accidental rate, the metallurgical trades expose the workers to much physical strain, to dust and fumes, to extremes of heat and humidity, and often to industrial lights injurious to the eyes. Yet such exposure can be reduced to a minimum, without impairing efficiency if simple protective measures are introduced.

In addition to the specific occupational hazards, the feverish effort at production brings in its train the deteriorating factors of speeding up and over-fatigue, the study of which and consideration of proper remedies, has already attracted so much attention in the work of the Health of Munitions Workers Committee in England. This problem is also being studied by the Public Health Service.

It must be remembered, too, that for the best results, sanitary conditions must be secured in the total environment of the workers, for it is evidently not enough to provide a sanitary workplace, when during the hours of rest and recreation the worker is exposed to the dangers arising from defective community sanitation.

The conservation of the health of the industrial army is therefore a major problem in public health and should be solved by the effective and coordinate action of all the public health agencies of the country.

Because of the authority conferred by Congress on the U. S. Public Health Service to investigate insanitary conditions, because of the studies it has already made, and because of its facilities to study and advise in matters pertaining to the public health, in a national emergency, such as exists at the present time, this service may be regarded as the proper medium through which the Federal Government may unite and coordinate the health agencies of the country in order properly to protect the health of the industrial army.

Such concerted effort is rendered all the more necessary because the large numbers of physicians which are at present or will be on duty with the military forces will considerably diminish the number of those available for the protection of the health of the civil population. For this reason alone it becomes necessary, first, to diminish sickness by preventing it, and second, to increase the efficiency of the remainder of the profession in order to care for those who become sick in spite of preventing measures. Moreover, owing to the lack of standards of industrial hygiene, lack of uniformity in health organization and great differences in facilities for disease prevention in various parts of the United States, unless there be some concerted action to provide uniform measures of health protection we are certain to be faced with the problem of greatly diminished efficiency, because of preventable disease in war industries developed in areas where as yet a sanitary organization is not adequately provided. An adequate supervision of the health in war industries should embrace the following points:

1. The creation of minimum standards of in-

dustrial hygiene covering the important points in factory sanitation and prevention of occupational diseases and poisonings.

2. Sanitary supervision of premises, buildings, and processes of industrial plants engaged in supplying war materials to the Federal Government. Such sanitary supervision would include not only general plant sanitation, such as the securing of adequate illumination, cleanliness, water supply, toilet facilities, and the like, but also the supervision of processes in such manner as to prevent the incidence of occupational diseases, industrial poisoning, and rapid physical deterioration.

3. Medical supervision of workers in industrial plants. This would include (a) such physical examination of workers as may be necessary to prevent the spread of communicable diseases among the plant personnel and the selection of workers for jobs at which they may maintain the greatest efficiency in output on a minimum physical stress, (b) medical supervision of workers so that minor physical ailments would receive appropriate treatment at the plant, thus avoiding loss of time, or, in the event of serious illness, provide a correct and reasonable diagnosis, so that the proper medical treatment may be obtained at the earliest possible moment, having in view the restoration of the workers concerned to full earning capacity in the shortest practicable time.

4. The avoidance of industrial over-fatigue, (a) by adjustment of hours of labor, rest, and recreation to the type of work so that maximum output will be maintained from hour to hour, from day to day, and week to week.

5. The institution of a campaign of education in personal hygiene by personal contact with workers so as to obtain their full co-operation in the general sanitary measures designed for their benefit.

6. In addition to the activities directly concerned with industrial sanitation and plant sanitation, collateral studies should at the same time be carried on with a view further to improve and increase efficiency and safeguard the health of the industrial workers. Such studies would include the relation of fatigue to the particular industry or process concerned; the influence of proper rest periods; the elimination of superfluous mental and physical stresses incident to the process or occupation; the efficiency of sanitary precautions adopted in the prevention of occupational diseases, the object of such studies being to eliminate superfluous, while maintaining adequate precautions.

7. While due attention to sanitary conditions within the plant will assist greatly in maintaining a continuous state of health on the part of workers, it is evident that attention must also be paid to community sanitation in industrial centers actively engaged in the production of war materials. It will avail but little to institute ideal sanitary conditions in industrial plants if at the same time there exist in the community environment of the workers such conditions as defective water supply, crowded and insanitary housing conditions, surface privies, inadequate facilities for garbage and waste removal, and the like. It will, therefore, become necessary in connection with

any general scheme for the protection of the health of the industrial army to play an active part in promoting community sanitation in industrial communities.

8. Nor must we lose sight of the moral side of bodily health. Measures which will remove deteriorating mental states, such as discontent, apathy, monotony, absence of mental stimuli, play no small part in reinforcing other measures for the protection of the health previously outlined.

As soon as minimum standards of industrial hygiene have been prepared, it is clear that the program as outlined above could be realized by active cooperation of State and local health agencies and State departments of labor with the Federal Government through the Public Health Service, active as a unifying and coordinating agency. In this manner we would realize in practice the attitude always maintained by the federal to the State and local health agencies, namely, an attitude which supplements and stimulates but does not supplant State and local activities. There is at present pending in Congress a measure by which all this may readily be brought about. This measure, known as Joint Senate Resolution 63, creates a reserve of the Public Health Service in which may be commissioned all persons skilled in sanitary science, and which empowers the Public Health Service to do two vitally important things: (1) to sanitize ports and places at or near which military forces are mobilized or are to be mobilized, and, similarly, ports or places at which industrial forces are mobilized or to be mobilized: (2) it empowers the Public Health Service to cooperate with and make effective the health agencies of the United States. The passage of this bill would at once enable the Public Health Service to expand to meet the public health situation which now confronts it. The present march of events in Europe, the urgent desire felt by all of us to see our country throw its potentially invincible resources of man power and materials into one concentrated victorious effort surely demand that no stone be left unturned to secure this great result. The adequate protection of the health of the industrial army must be regarded as an essential factor in this effort.

AID FROM THE MEDICAL PROFESSION IN THE PREVENTION OF DISEASE IN WAR INDUSTRIES*

By ALFRED STENGEL, M.D.,

PHILADELPHIA, PA.

PROFESSOR OF MEDICINE, UNIVERSITY OF PENNSYLVANIA

THE term War Industries is here used in a sense more comprehensive than is implied in the name Munition Works, and includes a great variety of occupations, such as shipbuilding, iron and steel works, textile factories, and a large number of others not so directly related to the necessities of war. In general terms, we may consider as War Industries all those occupations which will be required to supply national necessities, and in which

*Read before the New York Academy of Medicine, March 7, 1918.

all efforts will be put forward to secure the maximum output consistent with the physical welfare of those employed. Some of these, such as munition plants and shipbuilding plants, will frequently be in somewhat isolated positions and under quite complete governmental control, not only at the shops but also in the housing areas where the workers live. In the case of these, the supervision of the health of the employees will be relatively simpler and more effective than in the case of the large bulk of industries located in the midst of crowded industrial centers, their workmen living near or at a distance from the works, but in closer contact with the general community than is the case with the employees of isolated plants. The aid which the general medical profession may render in the prevention of disease among war industrials will be of especial importance in the case of these scattered plants; in the segregated ones an official medical organization under governmental control can more readily supervise the whole matter.

Before we turn to the details of the kind of aid the medical profession can render it is well to outline some of the assumptions that may be made regarding measures of prevention of disease at the source. The outside medical profession can be of little aid here except by assisting in the instruction of workmen and their families. The important causes of diseases originating in industries are: fatigue, impure and dust-laden air, improper heating, lighting and ventilation, traumatism and infection, various forms of poisoning incident to the occupation, and crowding or contact with masses of human beings. I leave out of consideration entirely the question of industrial accidents.

1. Fatigue very properly occupies the first place in this list, though I have not attempted to set the others in any order of relative significance. But fatigue, without question, leads all others, and is the underlying cause that occasions the reduced resistance or increased susceptibility to infection as well as to various other direct causes of disease. The tired man or woman most readily falls the victim to conditions that might otherwise prove innocuous. Leaving out of consideration the ulterior effects of fatigue in the causation of disease, this factor stands out prominently in the economic consideration of labor, because fatigue is, after all, the important cause of inefficiency. The regulation of the hours of work, the institution of rest periods, the insistence upon sufficient time for meals, the arrangement of chairs and stools, work benches, and other appliances to cut down unnecessary tire, these are some of the axioms in the scientific management of industrial plants. The number of hours of work appropriate to men, women, and children is gradually becoming a matter for direct and scientific determination. That workmen will actually accomplish more work in shorter working days or weeks, and with determinably less fatigue no longer surprises any one who has followed the literature of the last few years. The figures must naturally vary with the type of work, as well as with different individuals, but broad rules can be laid down. It is natural, therefore, to assume that definite regulations will fix the hours of work subject to partial modifications in selected cases.

2. That every appliance for proper lighting, uni-

form heating, movement of air, and elimination of dust and noxious fumes will be installed with the same care as safety devices to prevent the more obvious "industrial accidents," may be assumed as constituting a second group of regulations. I single out the matter of lighting for an added comment because of its special bearing on fatigue. Work in ill-lighted shops is demonstrably more fatiguing to the general nervous system than in an establishment of proper modern construction.

3. Cleanliness, with the resultant healthy condition of the skin, is a factor in the prevention of infection that deserves a more thorough appreciation than it has received. Every modern plant is provided with proper wash rooms, toilets, and even showers or bathrooms, and in many cases time out of the working day is allowed for their regular use. In certain industries this should be strictly enforced. Where contact with dangerous poisons cannot be wholly avoided, even with gloves, masks, or other devices, the propriety of such a regulation is obvious.

4. Crowding is used here in the sense of the massing together of people rather than to indicate a lack of cubic space of the workrooms per person. The avoidance of the latter is, of course, assumed; but the possibility of diseases spreading rapidly among masses of men not subjected to grossly unsanitary overcrowding is a factor of importance in industries. A counterpart of what is here in mind has been repeatedly observed in camps, where the periodic admission of new recruits from civil communities is followed by waves of increased morbidity. The danger can be obviated only by greater strictness in observing and treating minor conditions among such masses. The First-Aid Department of establishments has one of its important functions in this connection. Carefully prepared health cards of individual workers, and their utilization for the recording of what ordinarily seem trivial complaints, should form an essential part of the work of the First-Aid Department.

Closely related to the matter of the health record of industrials is that of his proper selection. The emergency of war work makes imperative what has always been recognized as desirable—that men, women, and children employed in any form of labor should be classified according to their physical standards and general adaptability. Certain individuals are as unfitted for one type of work while suited to another as other individuals are adapted to the reverse conditions. It is, of course, manifest that only broad generalizations can be made, and the experience of the foremen and the local medical corps must decide after considering individual conditions.

5. Food. Though the nutritional requirements of laborers are an essential to their physical wellbeing and consequent productiveness, I did not place this item among the conditions calling for regulation, because it, after all, pertains to the outside life of the worker; but as one meal at least is eaten during the working day and at the works, it is impracticable to ignore this question on the assumption that properly paid workmen will provide themselves with sufficient and suitable food. Experience has shown that even under the conditions of unusually high pay prevailing in war industries it is

erroneous to assume that workmen will come well fed, and practice has shown that economically it pays to establish canteens and even to assess the industry with the cost of maintenance, and, in large part, of the food itself. Perhaps the need in this country may be less than in England, or elsewhere in Europe, where many workmen have been in the habit of starting the day's work before their first meal, or breakfast.

Assuming that all proper regulations have been adopted to insure the right selection and classification of workers and to prevent overfatigue and disease at the plants, the next step is that there shall be a prompt recognition of disease as well as of overfatigue that may occur despite these regulations. It is at this point that the aid of the medical profession begins, and I repeat what I have said before, that outside physicians can obviously be of use mainly in connection with plants situated in the midst of crowded communities and operated by workmen whose homes are scattered about the whole community. It is evident that family physicians come in closest touch with people of all classes of society, and are in especially favorable relations with workmen and their families to aid in the campaign against disease by instructing people in the matters of personal and domestic hygiene which are so fundamentally important in the preservation of health. The best-thought-out plans of protection against the development of diseases at the places of work must of necessity fall far short of what is desirable if the home life of the workmen and their conditions generally during the hours of the day when they are not at work are unfavorable. Rules and regulations will accomplish much less to correct such evils than will the personal interest of the family physician.

That effective aid may be given by the doctors of the community it is necessary that they have knowledge of the conditions resulting from the industries, and also that they be as well informed as possible regarding industrial medicine generally. A number of new diseases have made their appearance in connection with the manufacture of modern munitions, and with some of these the medical profession is not yet familiar. Among other conditions, T.N.T. and Tetryl poisoning, and conditions local or general resulting from picric acid, nitrous fumes, fulminate of mercury, and other explosives, or their subsidiary ingredients, are of special importance. After these diseases have become well developed the symptoms are marked enough, but the earlier symptoms, which are precisely the ones which would first come under the notice of the family doctor, would scarcely arouse the suspicion of a physician unfamiliar with the subject. That this is no mere supposition I can best show by reporting that within my own knowledge in the last two or three years a number of instances of what were regarded as rather obscure diseases have occurred in parts of New Jersey, Delaware, and Pennsylvania, at some little distance from the munition plants on the Delaware. To those who were familiar with Industrial poisoning, the connection between the symptoms and the occupation was clear enough but the cases were not promptly diagnosed and in some a second or third poisoning was allowed to occur. No doubt the absence of the workman

from his occupation was regarded at the works as due to the alleged minor causes—bilious attacks, grip, colds or whatever the diagnosis may have been. It is evident that the first step to be taken is one of publicity and this might very well take the following forms:

1. Repeated meetings of local medical societies to arouse interest in industrial diseases generally, and especially to extend among physicians a knowledge regarding the more important diseases. In such meetings, emphasis should of course be laid upon housing, diet, recreation and rest, and other matters pertaining to the home life of industrial workers, conditions over which family physicians, through their advice, have more control than public authorities.

2. The preparation and wide distribution of brief but carefully written descriptions of industrial diseases with information regarding safeguards, treatment, etc. It would be an advantage to have these of uniform size and numbered and punched for temporary binding between cardboard backs.

3. Establishment of public clinics for industrial diseases, equipped for proper scientific investigation, as well as treatment of patients. Some special publicity might properly be given such clinics for the sake of stimulating interest and courses of instruction for physicians should be arranged.

4. In line with the subject matter of No. 3, it would be a timely advance in medical teaching if all medical colleges established special courses in industrial medicine, and large general hospitals gave more specific attention to this important matter.

5. Rules should be made by the public health authorities, in co-operation with the National Council for Defense, requiring as an emergency measure the reporting of certain classes of cases occurring among workmen in war industries; and it would perhaps be well if in addition cards were issued to physicians for the report of all conditions medical or surgical among such workmen. Supplementing these returns of physicians, there should be reports of special inspectors who would investigate hygienic conditions at the homes of workmen. Though some of the suggestions I have made may seem to involve encroachment upon the private rights of workmen and also to imply a considerable extra labor on the part of physicians, it will no doubt be found that all parties will loyally yield to the necessities of the times.

1728 SPRUCE STREET.

SURGERY IN ASSOCIATED STIGMATA OF DECLINE.*

By ROBERT T. MORRIS, M.D., F.A.C.S.
NEW YORK.

WHEN man began to rise upon his hind legs, either as a terrestrial or as an arboreal primate, his anatomy had to adapt itself to a posture for which it was apparently not intended by nature. We anthropocentrics assume that something unforeseen by nature took place and our postulate is based upon the fact that an engineer observing

*A paper read before the Surgical Section of the New York Academy of Medicine on March 1, 1918.

the anatomy of man finds that it is inferior for its purposes as compared with the anatomy of man's phyletic cousins among the anthropoid apes. The defects of man's anatomy are evident in his weak-walled inguinal canals, his badly arranged sacroiliac joints, the necessity for bowel contents to run up hill in the ascending colon, and in many other defects which need not be enumerated here. Suffice it to say, that the erect posture obliges man to carry numerous obstacles to good anatomical development.

Man is gregarious by nature, with a tendency to form urban populations. Under these circumstances he is freed from many features of contest with nature and like domestic animals or cultivated plants under similar conditions has a tendency to reach cultural limitations in his various nations. These nations come and go like varieties of cultivated plants and animals. When cultural limitations are being approached in man there is a tendency toward arrested development of various organs, and arrested development of various organs added to natural obstacles represented by man's anatomy results in mental states which are more or less abnormal. The reason for this is because structure and function are closely allied. Some of the philosophers tell us that structure and function are simply phases of the same thing. So much for the abstract feature of the proposition.

Concretely, a patient with fibroid degeneration of the appendix who has his appendix removed may tell us that he has not received any benefit from the operation. What does that mean? It means that in his case the fibroid appendix presumably represented one of the stigmata of decline, and this was only part of a picture in which the surgeon might have found associated stigmata of decline in the presence of a high arched palate, a gunstock scapula, and in relaxed peritoneal supports. Associated with the tangible and patent stigmata in this case were probably defective glands furnishing internal secretions, the enzymes of which were essential for the well-being of the individual. Removal of the fibroid appendix removed only one factor in the patient's troubles, and not a very important factor. After such an operation the patient is commonly benefited for a few months. A part of this benefit is psychic in its nature and dependent upon principles which allow Christian science, or any other suggestive method, to furnish stimulus which is more or less potent for increasing the well-being of the individual temporarily. Much depends upon the personality of the surgeon in such a case. There are men whose patients usually gain in weight and in good spirits no matter what is done to them, and there are others who do not happen to carry any such therapeutic manner and presence.

Not long ago I listened to an address by an oral surgeon who believed that many cases of mental derangement could be relieved if non-erupted molars were removed. He was no doubt correct. But he failed to take a comprehensive view and to say that removal of impacted molars from a large number of patients with mental derangement would, on the whole, be unsatisfactory in therapeutic effect. Impacted molars are stigmata

representing arrested development. Most of us carry some stigmata, and most of these are unimportant. If the oral surgeon had said that patients in whom associated stigmata of decline were strongly in evidence made little response to treatment so far as mental disturbances were concerned, we would have listened more intently to what he had to say concerning the few selected cases.

A loose kidney commonly represents a stigma of decline and is very apt to be found in connection with associated stigmata. Fixation of the loose kidney in well-selected cases is one of the most satisfactory operations in surgery, but fixation of a loose kidney associated with other stigmata that are markedly in evidence is so unsatisfactory that the operation has fallen into disrepute among men who have not made themselves familiar with the quantitative method of exact science—with that method which deals with parts and wholes and which assembles all testimony before arriving at conclusions.

Neuroses and psychoses are particularly apt to appear in patients carrying associated stigmata of decline which may be readily observed and tabulated by the diagnostician. Sometimes the influence produced by the peripheral irritation going with a fibroid appendix or a loose kidney or a sagging colon furnishes the precipitating factor for the patient's nervous or mental derangement. It is not the causative factor. Please note my insistence and emphasis when distinguishing between a precipitating factor and a causative factor. Patients with associated stigmata of decline represent a group highly susceptible to the influence of peripheral irritations and of focal infections.

Surgery which does not comprehend any one such case as a whole, may sometimes incidentally bring about spectacular benefit. The surgeon then is in danger of generalizing from insufficient data and he may proceed to operate in cases which he believes to be similar to the one receiving benefit, but with disappointing results. There is no doubt that properly directed surgery in carefully selected cases offers a very large and promising new field in psychoses and neuroses, but unless note is made of the character of associated stigmata present in any one case, progress will be halted by that sort of justified opposition which will come from the conscientious physician.

616 MADISON AVENUE.

CHRONIC PNEUMONIA; REPORT OF A CASE.*

By STANLEY L. WANG, M.D.,

NEW YORK.

CHRONIC non-tuberculous pulmonary lesions are of interest because of the difficulty of distinguishing them from chronic pulmonary tuberculosis. Such conditions are, as a rule, first diagnosed tuberculous and later, after prolonged observation, the proper diagnosis may be made. These cases are usually grouped together under the common heading, chronic non-tuberculous pulmonary disease, but it is desirable to classify them for the different types are distinct clinical entities.

The following case of chronic pneumonia is reported from the Sea View Hospital.

representative of one important group of chronic non-tuberculous pulmonary diseases.

Female, white, age 19, single, houseworker. Measles, scarlet fever and whooping cough in childhood. She had always been very healthy before her present trouble. In March, 1914, she got wet in a rain storm, after which she was confined to bed for a little more than a week, with a cough and bloody expectoration, fever and a sharp pain in her left lower chest. She seemed to improve very slowly, and after a short time some friends sent her to Maine for her health. She remained in Maine during the summer of 1914 and was not improved, her cough, dyspnea, weakness, and periods of fever confining her to bed at times. She returned to New York in December, 1914, and was admitted to a hospital where a diagnosis of far advanced pulmonary tuberculosis was made. A few weeks later she was transferred to Sea View Hospital, Staten Island, New York, with the provisional diagnosis "far advanced pulmonary tuberculosis probably complicated by small left pleuritic effusion." Her subjective symptoms at that time were frequent productive cough most marked in the morning, raising 150-200 c.c. of purulent sputum which was occasionally blood-streaked and usually foul. She practised postural drainage of her sputum, inclining her head and shoulders downward over the edge of the bed each morning before arising, thereby raising about one-fourth of her daily excretion. Her strength was much diminished although she was able to walk. She had dyspnea and vertigo on slight exertion. Her weight was 89 lbs., having lost about 40 lbs. since her illness began. Occasionally she had fever up to 102° F., although she frequently had afebrile periods of several days' duration.

Physical examination showed a flattened chest with respirations more obvious on the right side. The left base had one-half inch less expansion than the right base. There were areas of consolidation, probably pleuritic, signs of cavitation and many large moist râles in the left lower lobe, extending into the left upper lobe. The heart was drawn a little to the left and the second pulmonic sound accentuated. Her fingers and toes were clubbed. The skin and subcutaneous fascia seemed well nourished and of good color.

The sputum was always negative for tubercle bacilli, and an attenuated type of pneumococcus was the most abundant organism. Tuberculin tests and Wassermann reactions were negative, also was the blood cytology.

During her stay of a little more than one year in this hospital she progressively grew weaker and her symptoms were unchanged although they showed occasional exacerbations. She died during January, 1916, and Dr. L. Achard performed the autopsy and the pathological examinations. The findings were "chronic interstitial pneumonia with bronchiectasis of the upper and lower lobes of the left lung, most marked in the lower lobe; left subphrenic abscess; small splenic abscesses and an abscess in the right frontal lobe of the cerebrum." "The cerebral abscess was probably the immediate cause of death."

In reviewing this case, it seems probable that she had an attack of pneumonia in March, 1914, which did not resolve and it became a chronic condition causing progressive sclerotic changes in the lower left lung. The thickening of the pleura at the left base and the bronchiectasis there, indicate that the initial pneumonia was croupous with the usual accompanying pleurisy. The subphrenic, splenic and brain abscesses were very likely metastatic and probably shortened the duration of life, for the right lung was unaffected and was compensating.

The sequelæ of acute pneumonia are varied. In the most instances the disease is merely prolonged beyond the usual period and eventually convalescence occurs. Such cases as these often have a localized sclerosis at the site of the pneumonic process and this sclerosis is evidenced either or both by a slight chest deformity and changes in the auscultatory

and palpatory signs. These changes in the physical signs are often the basis of a wrong diagnosis of incipient tuberculosis especially in children. There is a small number of cases of pneumonia in which the disease becomes chronic such as the above described case. In these convalescence does not occur. The pneumonic process does not resolve and it becomes an indurating progressive lesion. Fibrotic organization of the pneumonic process takes place and very slowly extends into the contiguous pulmonary tissue. Bronchiectasis frequently supervenes as a result of the organizing induration.

The diagnosis of these cases, which is primarily a differential diagnosis from tuberculosis, is dependent on a close study of the history, course, physical signs and laboratory findings. The history and symptoms are very similar to those of chronic tuberculosis. There is probably a little less constitutional disturbance in chronic pneumonia. The skin and the subcutaneous fascia and the general appearance and nutrition are not affected to the same extent as is usual in chronic tuberculosis. Complications such as metastatic abscesses are not infrequent in non-tuberculous bronchiectatic lesions and they are a dreaded post-operative complication in the surgical treatment of these conditions. The chronicity is said to be greater than in tuberculosis. Bonney¹ observed this in this case. The lesions are usually basal and unilateral. Tuberculosis is almost always apical and it is extremely uncommon to find a lower lobe tuberculosis without apical disease although such may occur. The localization of the lesion in the lower lobes is often the first indication of a non-tuberculous disease. However, this localization is not limited to chronic pneumonia for syphilis, abscesses, infarcts and malignant growths, both primary and metastatic, are also found in this region. The physical signs are extremely variable and at times the lesion seems very dry where a short time before there were many moist râles. It is difficult to trace any relation between the symptoms and the variations in the physical signs for both seem to vary spontaneously and independently. The extent of the disease seems relatively constant and very little extension is noted, physically, over a long period of time. The absence of tubercle bacilli in the sputum is of course one of the chief aids in the differential diagnosis.

To be relatively certain that tubercle bacilli are absent, they should be searched for regularly and carefully, over a long period of time. Babcock, Lord, the younger DaCosta, Osler and Cabot lay emphasis on repeated sputum examination.

The frequency of chronic pneumonia as a complication of bronchial or croupous pneumonia is as yet undecided. Milne² found 10 cases of fibroid organization in 159 autopsies of pneumonia, of which 95 were croupous and 64 were bronchial. Of the 10 showing fibroid organization, there were 6 males and 4 females. These 10 cases represented examples of pneumonia where the usual process of resolution had failed and organization of the inflammatory exudate in the air alveoli of the lung by fibrous tissue had resulted. There were changes in the whole lobe or at least in large areas in 9 cases and in only one was the process patchy or bronchopneumonic in character. These findings were different from those of the majority of other

observers, some seventy in number, since Lænnec reported the first case in 1819. Most of these thought that chronic pneumonia usually followed bronchopneumonia and that it was most frequently found in the apex. Milne did not find this to be true in his case. He stated that these cases were of exceeding interest because of the lack of clinical data, the difficulty of diagnosis, the uncertain prognosis, the irregularity of symptoms, and the likelihood of complications.

Marfan³ described what he assumed were badly defined forms of pulmonary sclérosis with a pneumonic history. These cases were usually taken to be tuberculous, even though tubercle bacilli were absent, because of the bloody and muco-purulent sputum.

Jacobi⁴ mentioned a case of interstitial pneumonia occurring in a child four years of age. This was a colored girl who entered the hospital with the history of long-continued lobar pneumonia. She had fever, constant cough with copious, bloody, purulent, foul sputum, and a large cavity in her right lung.

Riesman⁵ described seven cases of a type of pneumonia occurring in young adults, which he classified as a type of lobular or catarrhal pneumonia, that became confluent and assumed a lobar distribution. All of his cases ended in recovery without a vestige of the morbid process remaining. The chief symptoms were a cough and moderate fever extending over a period of from several weeks to four months. The physical signs were entirely out of proportion to the symptoms. In the majority the lower lobe of the left lung was involved. Most of the cases were female and were between 10 and 20 years of age, although one was 27 and one 28 years.

The literature of long-continued pneumonia impresses one with the variability, within wide limits, of these conditions. In some, such as Riesman has described, convalescence occurs with no sign remaining; in others, after convalescence, changes in the physical signs at the site of the disease are noted, and still in others convalescence never takes place and the disease becomes a chronic process. The study of chronic diseases of the lungs necessarily is centered in tuberculosis because of its frequency, and this perhaps explains the reluctance in diagnosis and the obscurity of chronic pneumonia, which is only a part of the so-called group of chronic non-tuberculous pulmonary diseases. However, as Milne has stated, these cases are very interesting because of the difficulty of diagnosis, the uncertain prognosis, the irregularity of symptoms, and the likelihood of complications.

I wish to thank Dr. Edward S. Rimer, as this patient was on his service.

SEA VIEW HOSPITAL, STATEN ISLAND, N. Y.

THE PHYSICIAN BEFORE THE LAW IN SOME EUROPEAN COUNTRIES.

BY F. ROBBINS, M.D.,

NEW YORK.

FRANCE.—In his relations with the French law, the physician may appear (1) as an expert, (2) as a witness.

The summons may be verbal, but is usually in writing. It must contain the title of the magistrate who is the sender; the name, profession, and dwelling of the addressee; the place where he is to appear; the character of the transactions; the date. All these items may be needed for the control of the expenses at the time of settlement. For the same purpose, the judge (*juge d'instruction*) must note, at the foot of the summons, the actions performed by the expert and the time consumed in this performance. When the expert accepts the appointment, he first renders an oath before the judge to make his report and give his opinion honorably and conscientiously. The discharge of this formality is put down in writing in the proceedings, in default of which the report loses its character and has the value only of a simple testimony. Extreme importance is attached by the law to this condition. After the oath has once been rendered, it is no longer necessary to repeat it if the expert has to make further visits or reports in the same case; but these reports must mention the oath previously rendered. In certain special cases, where a consultation of experts is required or an opinion is needed on a common report, the judge may determine the points to be specified and the questions which require a decision.

Although, theoretically speaking, any doctor of medicine may be called upon as an expert, the summons will presumably be addressed, as a rule, to practising physicians only. Every general practitioner is bound to obey the summons he may receive from the courts. He must present himself, but before proceeding to an examination or an autopsy he has the right and the duty, if he feels himself incompetent, to inform the magistrate to that effect and to declare that he does not possess the knowledge required for the task with which the law means to entrust him. The physician must show his willingness, and when able to do so he will lend his assistance. But, if the case is difficult and the physician does not feel himself equal to the task conferred upon him, he should not hesitate to give this declaration, so as not to incur any responsibility. After the expert has accepted an obligation, he must discharge it completely and carry out all the rulings; otherwise, he may be fined and even made to pay damages. If summoned as a witness, he must obey this injunction. However, the physician who has witnessed the deed or attended to the patient may refuse to testify if he has promised secrecy. Otherwise, he must answer as a witness. A physician who is summoned as a witness must not fail to appear. Failing to obey the summons, he is punished according to the common law. It is understood that he cannot answer in regard to points which seem to him to violate professional secrecy.

The law has distinctly specified the differences existing between the *expert* and the *witness*. The

witness states a fact, the expert expresses an opinion. The witness of a deed, act, or crime is the only person able to say what has occurred, what he has seen and heard; hence, he cannot be replaced. The expert may be replaced, any other expert being able to accomplish the same task and to assist the ends of justice. A witness who is convicted of not having spoken the truth is punished by the law. The expert cannot be prosecuted for having expressed an opinion which is sometimes contradictory to that of another expert. He alone is master and judge of his statements or opinions. Experts must have pursued special studies, and they must show intelligence and judgment. They alone can appreciate the weakness of their knowledge and compare it to the exigencies of expert testimony. The ends of justice are better served by prudent reserve than by ridiculous arrogance and presumption.

The law makes a distinction between fees due to medical experts and witnesses. The expert receives special fees for visits, reports, etc., but the physician summoned before the courts on account of his statements, visits, or reports is no longer considered as a professional, but becomes a general witness and is remunerated accordingly.

Intervention of the Physician in Criminal Proceedings, Upon Request of the Defense.—The physician is not invariably summoned by the prosecution, but may be called upon to render testimony at the request of the defense. These cases require extreme tact and circumspection, and all intervention should be governed by the greatest caution. The physician may be consulted by the defense in civil or criminal proceedings. He has the right, and even the duty, to interfere in a process, whenever he believes his intervention necessary for the establishment of the truth. Serious considerations and the idea of preventing the perpetration of an injustice should alone cause the physician to lend his support to the defense.

ENGLAND.—A medical man acts as a common witness when he gives evidence as to the condition of a wounded person examined by him. In such a case his duty is to describe the nature of the wounds, the general condition of the patient, and other circumstances that he observed at the time he made the examination. A common witness is obliged to give evidence if legally summoned to do so.

The obligations of the expert witness are not so easily defined as those of the common witness. Hypothetically, the knowledge possessed by an expert who has no personal acquaintance with facts relating to a given case is his own property, and therefore he ought not to be obliged to part with it against his will. This view has been taken by more than one judge. Lord Campbell ruled that a scientific witness was not bound to attend on being served with a subpoena. Justice Maule ruled that an expert is under no obligation to give evidence before a court of law. Unfortunately for experts, the difference of opinion of which they are proverbially accused pervades the judicial bench. Other judges have ruled that wilful neglect of a properly served subpoena constitutes contempt of court. In the face of decisions so adverse, it is difficult to determine what the law on the subject really is.

It is probable that an expert who had no personal acquaintance with a case might neglect a subpoena without rendering himself liable to attachment for contempt of court, but he might render himself liable to an action for damages. Such an action, though futile so far as obtaining a verdict goes, would subject the defendant to much trouble and to some pecuniary loss in defending it. Having regard to the uncertainty of the results, the safest course would be to obey the subpoena under protest.

Previous knowledge of the facts of a case precludes a witness from taking any possible advantage of the status of an expert witness. There is no doubt as to the obligations of a witness so situated; he must obey a subpoena in his capacity as a common witness, although the evidence he is going to give may be of an expert character.

When giving evidence solely as an expert, the witness acts as an interpreter of facts without having personal knowledge of them. Usually, a medical witness acts both as a common and as an expert witness, his skilled or expert opinion being founded on facts that he himself has observed.

Before giving purely expert evidence—that is, evidence founded on facts of which he has no personal cognizance—it is necessary for the witness to have heard the facts on which he expresses an opinion stated on oath before the court.

SCOTLAND.—There are certain differences with regard to legal proceedings in Scotland as compared with England.

The Procurator Fiscal performs the duties undertaken by the Coroner in England, but without a jury. If a dead body is found, or a case of suspicious death occurs, the Procurator Fiscal, on being informed, has the power of directing a medical man to make an examination of the body and to forward him a report dealing with the case, all such reports being certified by the reporter "on soul and conscience." If the medical examiner is satisfied with an external examination, he may certify to the Procurator Fiscal without making an internal examination. If a complete examination is requisite, the Procurator Fiscal issues a warrant to the medical practitioner who has already seen the case, and usually associates with him another practitioner of experience. The warrant is countersigned by the Sheriff or Justice and empowers the holder of it to take charge of the body and to make such examination as the law requires. To ensure completeness of examination, the Crown Office in Scotland issues a form of instructions to medical inspectors, which contains elaborate directions for making the necropsy.

A medical practitioner, whether previously acquainted with a given case or not, cannot refuse to be precognosed (privately interrogated) if duly cited to that effect. Refusal is met by a further warrant and in case of contumacy by imprisonment.

The fee for attendance at High Courts of Judiciary or the Sheriff Criminal Court is a guinea per day, if the court is held in the town in which the medical witness lives. If the witness comes from a distance he is allowed two guineas per day, both for the actual attendance at court and also for each day occupied in traveling to and fro, with a guinea per day for traveling expenses.

SWITZERLAND.—The law in regard to the practice

of the medical professions in the Canton of Bern distinguishes by the ruling of March 14, 1865, between physicians, druggists or apothecaries, dentists, and midwives. These various categories of medical experts may be employed exclusively as functionaries in the scope of their degrees or diplomas. For the individual medicolegal examinations the requisite medical experts are nominated by the examining judge. In the Canton of Bern the judge has entire freedom of choice between the registered medical persons (free system), whereas in certain other Swiss cantons (Vaud) he is limited to definite medical functionaries (restricted system, likewise obtaining in Germany and Austria). The number of experts to be summoned for the medicolegal investigations is determined by the examining judge, with the reservation that two experts are summoned for the more important cases and only one expert for the less important ones. Article IX of the Berner Strafprozess rules that two experts should be summoned in a general way, one expert sufficing in misdemeanors and infractions of police regulations.

The great majority of examinations on the part of medical experts in criminal cases take place in the course of the preliminary examination, which is not public; hence the persons concerned in these preliminary proceedings are held to preserve secrecy in this connection. Article XCIII of the Berner Strafprozess rules that all persons assisting in these closed proceedings must maintain their secrecy inviolate.

ITALY.—The Medical Faculty of Rome, in view of the distressing spectacle furnished by the rendering of expert medical testimony on the part of the prosecution and the defense in recent criminal proceedings, unanimously voted, at a meeting on June 20, 1905, for the institution of a radical reform of expert medicolegal testimony, by the establishment of a single expert committee, for both the prosecution and the defense, with suppression of the expert debates in public proceedings, in the interest of science and justice. The entire faculty of the kingdom was invited to take similar action.

The Liguro-Piemontese Section of the Società Freniatria Italiana, meeting of June 29, 1905, approved the following order of the day: The Liguro-Piemontese Section of the Società Freniatria Italiana, following the initiative of the Medical Faculty of Rome, votes that in every process in which expert medicolegal evidence may be required these testimonies should be audited by a Single Expert Committee, and that in those cases in which the expert committee fails to agree, on account of marked differences of opinion between its members, an arbitrator should be nominated and selected by a competent body, such, as, for instance, the Academy of Medicine or the Freniatrial Society.

Notwithstanding the opinions repeatedly expressed in the past, it appears that in the amendment to the Criminal Code the suggestion of the Single Expert Committee has not as yet been accepted and sanctioned. Meanwhile, it is a good sign that these opinions are being more and more urgently expressed, especially since in the Ministero di Gracia e Giustizia there already exists a

special bill, submitted several years ago, for the rational and critical regulation of the medical expert system. Moreover, it appears that at present a bill is under preparation for the reform of criminal proceedings in which the system of the expert evidence is likewise to be amended. The solution of the problem will be further assisted by the establishment of medical judicial experts, which was recently insisted upon by the voting of the Superior Consiglio di Sanità. This will be facilitated by the institution of "finishing" courses for the various specialties, as sanctioned by the new university schedules, and will be supported by the Ministro dell' Istruzione.

Medicolegal Notes.

Privileged Communications.—In an action for personal injuries the Idaho Supreme Court holds that under the state statute forbidding a physician to be examined as to any information acquired in attending his patient the acquisition of which is necessary in order to enable the former to prescribe or act for the latter, all statements made to a physician by his patient while the former is attending the latter in a professional capacity, for the purpose of determining his condition are privileged, although they have nothing to do with the patient's treatment or the determination of his injuries. It is immaterial in the application of the statute that the physician was hired by the patient's employer. The patient does not waive the privilege by testifying that in caring for his injuries he followed the physician's advice.—*Brayman vs. Russell, etc., Lumber Co.*, 169 Pac. 932.

Right to Practise Optometry.—In an application for a writ of habeas corpus by one committed for violating the California statute regulating the practice of optometry the petitioner contended that by virtue of his being the holder of a certificate entitling him to practise osteopathy he was by the terms of the act itself regulating the practice of optometry excepted from its prohibitory provisions. The exception referred to is contained in section 10 of the act (Stats. 1913, p. 1097), and is in the following language: "The provision of this act shall not be construed to prevent duly licensed physicians and surgeons from treating or fitting glasses to the human eye." The question to be determined was whether an osteopath, licensed under the statute regulating that profession, was within the purview of the optometry law a licensed physician and surgeon. The California act of 1913 regulating the practice of medicine and surgery (Stats. 1913, p. 723), provides for the examination of persons desiring to follow these professions, and for the issuance of two forms of certificates, one designated a "physician and surgeon certificate," and the other a "drugless practitioner certificate." The district court of appeals said: "The distinction between these certificates is quite marked, and they are issued as the result of a different examination; and it is very apparent to us that the term 'duly licensed physician and surgeon,' as used in the section of the act above quoted, has direct reference to the holders of the former class of certificates to the exclusion of the holders of the latter. The cases cited by petitioner from other jurisdictions holding that an osteopath may be said to engage in the practice of medicine and surgery have, in our opinion, no application to the facts of this case, where the question is much narrower and is one of statutory construction. Under our statute we are clearly of opinion that the petitioner is not a 'duly licensed physician and surgeon.' It results from this conclusion that the writ should be discharged."—*Ex parte Rust*, 160 Pac. 1050.

Military Medicine.

Mitral Stenosis in the French Army.—Denis refers to earlier published statements of his to the effect that mitral stenosis sometimes passes unnoticed. Since that period he has learned that the proportion is larger than was at first believed. In addition to the contingent due to congenital and youthful endocarditis there are other cases without clinical history, which are first manifested after prolonged marching and other forms of strenuous exertion. These soldiers present evidences of disturbed pulmonary circulation—bronchitis, hemoptysis, etc.—with complication of the general health. In such cases a cardiac lesion is often unsuspected and the patient is looked upon as tuberculous. These mitral subjects are often sickly and the physical signs may suggest tubercle. One soldier was sent back as unfit no less than five times in six months. Life at the front invariably brought on, within a few days, a congestion of the lungs which subsided after a period of rest. Such a state of affairs should have been impossible, for auscultation should have at once disclosed the presence of a cardiac lesion. There are other cases which are complicated by old recovered or latent tubercle, upon which substratum of the cardiac lesion has developed. Even these should have been promptly identified.

When the mitral lesion causes other than pulmonary symptoms diagnosis may be simplified, but in some subjects we see only general failure of health, perhaps, with gastric symptoms. The general reaction may be expressed as intolerance to exertion, the subject tiring readily. A systematic examination readily excludes tuberculosis. The sputum is free from bacilli, there is no temperature rise, and the x-ray is negative. To study the heart rhythm the usual listening areas are not sufficient and the author prefers the left intercostal space near the sternum with patient recumbent. The discovery by palpation that the apex beat is within the nipple line is of great value because it at once excludes all other types of official lesion. The rhythm should be correct, despite the altered tones. There is, of course, a systolic—more rarely a presystolic—murmur with duplication of the second sound, imitated by the author as “roun, ta ta.” The systolic murmur, however, does not always give the same sound, and there is a distinction between two tones expressed as “roun” and “oun.” At the apex the first sound may be represented as “brouté.” The blood pressure is low.

In several ways this lesion is notably atypical; and in the absence of autopsy material the author is puzzled to account for its presence. To what extent is it a cause and to what an effect? Is the heart involved in a vicious circle? The soldiers often state that they have always been weak and timid even from the days in which they were spoken of as tied to the maternal apron strings, or preferred the quiet pastimes of girls to the rougher ones of boys. Cross questioning may bring out a history of a stitch in the left side or a constricted feeling in the chest. Everything points to a not uncommon latent condition lighted up by war hardships.

Amputation in View of Future Prosthesis.—

In the *Medical Journal of Australia*, January 26, 1918, Lieut.-Colonels Victor Hurley and Hugh R. G. Poate write on the adaptability of the various stumps met with for the fitting and effective use of an artificial limb. Protest is made against the “guillotine” amputation, so frequently carried out through the healthy tissues of a limb some distance above the original lesion. This operation is a most pernicious one and can by no means be regarded as a life saving measure, the usual excuse for its performance, as shock is increased by the further damage to healthy tissues. A re-amputation is generally a necessity later on, and a further length of limb must be sacrificed. When a limb has been badly smashed the ideal operation is a section made through the seat of fracture, and whenever possible an attempt should be made to leave flaps of some sort, even if they have to be sewn back to allow of a full exposure.

Stumps in general should be carefully examined before being passed for the fitting of an artificial limb. Bulbous and tender nerve ends are frequently met with. Often they are involved in the cicatricial tissue of the scar, by the contraction of which they may be displaced from their normal position. At times bulbous nerve ends can be felt which are not painful, but if there is any tenderness the nerve must be excised. Perhaps the most difficult situation to deal with is the brachial plexus in high amputations of the arm. The practice of firmly ligaturing all nerves with catgut seems greatly to minimize the development of end bulbs, due probably to the fact that the neurilemma is drawn over the ends of the injured fibrils and so diminishes their tendency to wander outside their limiting membrane.

As a rule, so long as the scar is freely movable over the end of the bone, and will stand an equal pull over the circumference of the limb without becoming ischemic, it will pass, even though it is wide or puckered. The mobility depends primarily upon the operator having been able to draw a good fatty pad over the end of the bone. It is not worth while suturing muscle, as it invariably atrophies, and only the fatty pad is left to cover the bone. If the scar is stretched and adherent it must be excised, the edges undermined and brought over without tension even though bone may have to be removed. Frequently broad, thin scar is seen, which even without tension, and certainly with it, will blister or break down; treatment, however prolonged, is of no avail, and excision must be resorted to.

Edema of the stump is frequently seen persisting for many weeks after an otherwise perfectly healed amputation and must be dispersed before an artificial limb can be fitted. Very firm bandaging with some massage and exercise of the stump usually dispels it in seven to fourteen days. The range of movement of the stump must always be carefully watched and attention must be directed to maintaining the full range of joint movement during the healing of the wound. If any contracture has developed appropriate measures must be adopted for its removal before a limb will be of any use. Bony spines are often seen resulting from an outgrowth of callus along tendinous insertions or intermuscular septa. They are met

with particularly about the lower end of the humerus and are especially common about the femur, along the *linea aspera*. If they cause any tenderness or pressure they must be removed.

Attention may here be drawn to the frequency with which tender spots, blisters, or ulcers develop over the crest of the tibia after the fitting of limbs when care has not been taken to round off this bony prominence thoroughly; but, as a rule, these troubles can be relieved by moulding of the leg bucket over the affected area so as to relieve all pressure.

The shortest forearm stump to which an artificial limb can be applied is one measuring 5 cm. from the tip of the olecranon. It is useless trying to save anything shorter than this, as a limb can be much more conveniently fitted to the stump of an amputation done through the upper arm, just above the condyles of the humerus. With forearm stumps of 5 to 10 cm. in length, excision of the origins of the flexor and extensor groups of muscles from the lower end of the humerus is of great advantage and in the very short stumps is a necessity. This procedure increases the weight-bearing area of the stump, by allowing the bucket to be fitted closely to the bony support. The stump does not tend to slip out of the bucket as it so often does if these muscles are left. There is no particular advantage to be gained from a long forearm stump; in fact, the best amputation is one of not more than 20 cm. in length.

Amputation through the elbow joint leaves the most unsatisfactory stump to fit with a useful limb. The end of the stump is too wide to slip into the ordinary upper arm bucket and it is difficult to arrange a workable elbow joint. It is much better to amputate just above the condyles of the humerus, as this gives the most desirable and easily fitted stump for the upper limb.

As in the case of short forearm stumps, so with upper arm stumps, the weight-bearing area can be considerably increased by excision of the humeral attachments and some of the musculature of the pectoralis major and latissimus dorsal muscles. If this does not give a stump of sufficient length to carry a bucket efficiently, then these cases should be fitted much in the same way as is done with a disarticulation at the shoulder joint. At first it was found difficult to fit these cases with a satisfactory limb, but if a moulded leather shoulder cap be made it can be incorporated with a limb provided that care be taken to leave sufficient space in the axilla for the clothes to fit comfortably. If there is a short upper arm stump the limb can be connected by a curved steel piece to the shoulder cap over the point of the shoulder with a joint allowing movements of flexion and extension. It should be situated over the greater tuberosity so as to be in the same plane as the center of the shoulder joint.

The shortest leg stump to which it is possible to fit a satisfactory limb is one resulting from an amputation at the level of the lower end of the tubercle of the tibia. Rather than to leave any stump shorter than this it is better to amputate through the knee joint. The best stump in the leg is one corresponding to the lower end of the belly of the gastrocnemius muscle. In any leg amputation

care should be taken to bevel and round off the crest of the tibia and to divide the fibula at least one and a quarter centimeters higher than the tibia, as it has been noticed that the fibula released from its spring contact with the lower end of the tibia apparently elongates and projects below the cut end of the tibia in a stump and may cause inconvenience. In short leg stumps it is sometimes of value, in order to fit a limb satisfactorily, to excise some of the musculature of the gastrocnemius in order to prevent the stump from pulling out of the bucket, which in such cases must embrace the stump very firmly. A good leg stump is, from the cosmetic point of view, the best we have for fitting with an artificial limb, as after a few weeks' careful practice the patient usually can walk so naturally that it is difficult to detect that he has anything abnormal about him at all.

Unlike the case of amputation at the elbow joint, an amputation through the knee joint affords a very satisfactory stump to fit. An artificial knee joint is a very satisfactory mechanical arrangement, provided that the hinge is centered properly at the level of the transverse axis of the joint, and efficient support is given by a well-fitting bucket to be laced up the center of the thigh in front.

In the case of amputation in the thigh the cardinal rule is to leave as long a stump as possible, for the higher the level of amputation the less satisfactory to the patient is the fitting of the limb. Experience has now proved that with all amputations through or above the center of the thigh it is necessary to order a pelvic band for attachment to the upper part of the thigh bucket. In such cases one must watch very carefully that the maker has adjusted the band correctly and placed the joint in the proper position. Soft, fat thigh stumps are unsuitable for a leather bucket, owing to the folding in and puckering of the skin, and in these cases it is more satisfactory if a well moulded wooden bucket is ordered. When the limb is being tried on one must see that the anterior superior iliac spines are in the same horizontal plane, so that the limb may be of the right length. Six millimeters is the maximum difference in level that may be allowed.

Health in the Camps.—The week's report on health conditions in the camps, issued by the War Department, under date of March 28, shows that the death rate among the soldiers increased from 182 the week before to 223. Pneumonia showed an increase in the National Army and regulars, but in the National Guard all epidemic diseases declined. Deaths in the Regular Army numbered 86, as against 71 the week before; in the National Guard, 20, as against 28; and in the National Army, 117, as against 81. Seventy-three of the deaths in the National Army and seven of those in the National Guard were caused by pneumonia. The National Guard camps reported 76 new cases of pneumonia; the National Army camps 287 new cases of this disease, as against 255 for the preceding week. The epidemic diseases are reported as being on the decline.

Advantages of a Pharmaceutical Corps.—At a

recent hearing before the Committee on Military Affairs of the House of Representatives, Dr. C. Madison Taylor, representing the Medical Society of the County of Philadelphia, advocated the establishment of a Pharmaceutical Corps in the military service, giving as his reason the fact that there were among the pharmaceutical profession a large proportion of highly educated experts in many of the same fundamental lines on which the profession of medicine is advancing. He expressed the belief that among the particular services a specially educated pharmacist could render were the following: He could supplement and contribute to the correlating of data for the surgeon; he could perform a large part of the clinical laboratory work. He could apply tests such as the Wassermann, Noguchi, Widal, etc., and he could keep all the material for those tests up to date. Many chemical problems were arising in connection with poison cases. He could prepare all special materials for such procedures as hypodermoclysis, blood transfusion, Carrel-Dakin solution, etc. He could examine water supplies and all articles of food and drink. One surgeon and two pharmacists could probably do as much good work as two or even three surgeons.

Red Cross Activities.—During the first two days of the great battle in the Somme district the American Red Cross sent vans to help take away the wounded, and they have been called to give special help to the refugees, 10,000 of whom are said to have passed through one place where a canteen is maintained. To meet this emergency the Red Cross supplied 2,000 tons of condensed milk, half a ton of coffee, 500 pounds of chocolate, and 2000 pounds of meat. On March 29 the American Red Cross transmitted to the British Red Cross a check for \$1,000,000, "to alleviate as far as possible the suffering caused by the battle now raging." John McCormack, in a flying tour of concerts for the Red Cross, has earned \$80,000. He expects to have \$100,000 when he completes his tour on May 1.

Red Cross House at Base Hospital No. 1.—A Red Cross house for convalescent soldiers was opened on March 30, in connection with the United States General Hospital No. 1, on Gun Hill Road and Bainbridge Avenue, the Bronx. This is the first of a number of similar houses now being built by the American Red Cross at the larger base hospitals. It is intended as a lounging and rest room for convalescent soldiers and an administration center for the Red Cross field director, through whom relatives may obtain accurate information as to the welfare of the patient.

Medical Officers Dismissed from Service.—Announcement is made by the War Department that officers of the Medical Reserve Corps, who were recently tried by court martial and found guilty of gross neglect of duty in failing properly to examine a private at Camp Funston who subsequently died, have been dismissed from the service.

Hospitals Chosen for Reconstruction Work.—Surgeon-General Gorgas announces that fourteen hospitals have been chosen for beginning the work of reconstruction of disabled soldiers returned from France. The hospitals selected are the following: General Hospital, No. 4, Fort Porter, N. Y., will care for the insane; General Hospital No. 7, Roland Park, Baltimore, will care

for the blind and deaf; General Hospital No. 13, Dansville, N. Y., will care for epileptics and neurotics; the Walter Reed Hospital, at Takoma Park, Washington, D. C., and the Letterman General Hospital, San Francisco, Cal., will make special provision for amputation work. Other hospitals chosen are General Hospital No. 2, Fort McHenry, Md.; General Hospital No. 3, Colonia, N. J.; General Hospital No. 6, Fort McPherson, Ga.; General Hospital No. 9, Lakewood, N. J.; General Hospital No. 14, Fort Oglethorpe, Ga.; Army and Navy General Hospital, Hot Springs, Ark.; Base Hospital, Des Moines, Ia.; Base Hospital, Fort Riley, Kas., and Base Hospital, Fort Sam Houston, Tex. Individual hospitals from this group will be equipped for special work in cardiovascular diseases, tuberculosis, neurological and other head surgery cases, for speech defects, general medicine, and other specialties. In making this announcement Surgeon-General Gorgas recommends the following policy in connection with the work of reconstruction and rehabilitation of disabled soldiers and sailors: "That hereafter no member of the military service disabled in line of duty, even though not expected to return to duty, will be discharged from service until he has attained complete recovery or as complete recovery as is to be expected that he will attain when the nature of his disability is considered." The best facilities for functional and mental restoration and occupational training will be provided at each of these hospitals.

Women in the Volunteer Medical Reserve Corps.—The Medical Board of the Council for National Defense states that women as well as men are expected to offer their services for the new volunteer medical reserve corps now being formed. Nearly 2,000, or about one-third of the total number of medical women of the country have already registered in the organization known as the American Women's Hospitals. Over fifty women physicians have already gone to France to work among the civilian refugees. The first work of the volunteer medical corps will be substituting for physicians called into war service and caring for the health of workers in supply and munition factories in the United States. They are likely also to be called upon for special work as bacteriologists, pathologists, radiologists, anesthetists, etc.

American Women's Hospitals Gets Ambulances.—At the daily luncheon of the Money Raising Committee of the American Women's Hospitals at the Biltmore on April 1 a gift of three motor ambulances was announced. One of these, manned by a squad of women physicians, was on exhibition before the Public Library at Fifth Avenue and Forty-second Street during the week.

Women Bacteriologists Wanted in the Cantonments.—It is announced that the army needs the services of 100 women bacteriologists to take the place of men in cantonment laboratories in this country. A practical knowledge of clinical pathology and laboratory diagnosis is required for the work. The salary is \$720 with maintenance, and \$1,200 without maintenance, transportation furnished by the Government. Applications should be made to the Office of the Surgeon General of the Army at Washington.

SANITATION OF THE EXTRACANTONMENT ZONES.

THE United States Public Health Service, in addition to its already multifarious tasks, has, as part of its war duties, taken charge of the sanitation of many of the extracantonment zones. In Public Health Reports of March 8, 1918, Surgeon S. B. Grubbe tells of the sanitary work being done in Newport News, Va., and vicinity. In addition to two large embarkation camps, which contain a large and floating military population, the Newport News Shipbuilding and Drydock Co. employs over 10,000 workmen, engaged mainly in Government work. In the district over which the service has authority there is a population of 100,000, an increase of 45,000 since the camps were formed.

So for the control of communicable diseases the first essential is their prompt recognition and reporting, and in recognition of this fact all the physicians in the district have been asked verbally, by letter, and through their societies, to report to the district health office all cases that are or are suspected to be communicable. Contacts are examined and proper measures to isolate carriers of disease and those already in the incubation stage are taken. Contagious diseases among troops and laborers on camp sites are cared for by the army, but there is the closest cooperation between military and civil health authorities, and the various camps report each day details of all cases.

Malaria and typhoid fever are both prevalent in the peninsula in the charge of the service, but the necessary steps are being taken to exterminate and prevent the spread of both diseases. Tuberculosis is also prevalent, but suitable precautions against it are being taken.

The disposal of excreta is conducted on primitive lines in Newport News and in the rest of the district. There are 1,500 privies or so, of unsanitary type and poorly scavenged, in the area under the sanitary domination of the service. Of course, this has offered constant danger of typhoid fever, and a new and sanitary system for excreta disposal will be installed. The water supply is not wholly satisfactory, and means will be put into force to remedy defects in this direction.

With regard to venereal diseases, while it is recognized that they constitute a most serious health problem their control has seldom been attempted, and efforts which have been put forth to do so have met usually with slight success or with absolute failure. However, with the necessity for military efficiency, the subject can be no longer ignored, and the lines of action are being drawn. These are: (1) Recreative amusements and education of the soldier, both within and without the camps; (2) the enforcement of laws against public and clandestine prostitutes both in brothels and on the streets; (3) the treatment of persons in the infective stages of these diseases with the isolation of patients that cannot be otherwise controlled. The fact is likewise well appreciated that education and publicity must necessarily play an important part, probably be the deciding factor, in the suppression of venereal diseases. Surgeon Grubbe concludes by stating that intensive extracantonment sanitation has been made possible by reason of the war, which has justified the expenditure of more money than the local committees could be expected to contribute. Among the troops this work should cause a decided decrease in physical disability that would otherwise result from communicable diseases, especially malaria and venereal infections. Upon the civil population it should act as a protection against infectious diseases brought in by troops which are gathered from all parts of the country. Especially important among these infections may be mentioned measles, diphtheria, and cerebrospinal meningitis. In addition, a great deal may be done to curtail the increase among the civil population of certain diseases, such as typhoid fever and tuberculosis, that thrive on congestion and poor sanitation. One indirect result of these efforts will be the advancement of health education. Those people who have experienced the comfort and satisfaction derived from good sanitation and the feeling of security afforded by a well-equipped health department that deals promptly and vigorously with all communicable diseases, will not be satisfied with the old fatalistic attitude that has been common in the country. In brief, war conditions will wake up the people of the country to the need for extensive and radical sanitary reforms.

ORTHODONTIA IN RESPIRATORY OBSTRUCTIONS.

THE treatment of dental malformations by the mechanical methods included in orthodontia is a comparatively new science, and because of the cost of this form of treatment it is at present available only to a few. The effect of dental malformations and occlusions on the shape of the face, of the jaws, and of the palate is now well recognized. It is likewise recognized that appropriate orthodontic treatment carried out in early life can remedy almost entirely the dental and bony malformations. Moreover, accompanying the bony changes due to

these orthodontic conditions, there is a narrowing of the nasopharynx and a vaulting of the palatal arch, directly causative of obstruction to breathing. Much of the obstruction to breathing found in young children and heretofore attributed to adenoid or intranasal obstruction is caused by this bony malformation, and is therefore not benefited by the usual operations for the relief of the obstructions. Anthropologically, the tendency to this bony obstruction is explained on the ground that in civilized races the development of the cranium takes place at the expense of the bones of the face. In the lower races dental symmetry and the absence of obstruction to breathing receives explanation on these grounds.

At any rate, before subjecting a child to adenoid operation or intranasal interference for the relief of obstruction to breathing, it is well to see whether or not the nasopharynx or the nasal passages are sufficiently patent from the standpoint of the bony structures enclosing them. The suspicion that the respiratory obstruction may have origin in the bony parts is, of course, much strengthened by the presence of the dental malformations caused by the lack of room on the dental bearing surfaces of the jaws. Indeed, there seems to be an entire narrowing of both upper and lower jaws so that the teeth have no room on them; and the palate will also be found to be unduly arched or vaulted. It can be seen that much of the so-called recurrence after adenoid operations is due to these conditions, the slight improvement, if any, being due temporarily to the increase of space from removal of mucous membrane and adenoid tissue thereon. The treatment of choice, when once the real conditions are understood, is the widening out of the upper maxilla by appropriate orthodontic appliances. The palatal arch, the nasal passages, and the nasopharynx are all considerably widened by this procedure, and improvement is usually very rapid and marked.

It can be seen that where the nasal obstruction and mouth breathing retard the physical but especially the mental development of the child, so that it becomes distinctly backward, benefit can be obtained only when orthodontic treatment is instituted early enough before the child has become hopelessly backward and unable to catch up. But in the case of the poor child, although the cause is recognized and the indications for treatment are clear, the cost of orthodontic treatment puts treatment out of their reach. Its only hope of receiving this treatment lies in the extension of the dental clinics now being so widely established so as to include this form of treatment.

PERFRIGERATIONS AND CONGELATIONS.

ACCORDING to Mazzolani in *Il Policlinico* for February 3, these lesions constitute a pathological accident of great significance in a warring army because a number of individuals are stricken at once. Nevertheless the number of victims is rela-

tively small, so far as the official records are concerned; and this appears to show that with proper equipment and care the condition is largely preventable. It should perhaps be possible to distinguish in advance the men who are unduly sensitive to the action of cold, and avoid exposing them. Again, timely treatment will also save a soldier who might otherwise become permanently incapacitated. The soldier must be taught to care for his feet and should be watched with that end in view. Cumulative cases of a severe type requiring amputation occur—the so-called mutilating epidemics due to cold, and come about in an insidious fashion. These are noticeable in conditions of hardship in which there is no opportunity to give attention to routine, as during the recent reverses in Italy.

The author goes extensively into the historical aspect of the subject. We know that in various campaigns the number of deaths from exposure to cold was very large and in the more recent wars we have records of the local effects. During the siege of Sebastopol there were 2,500 cases of freezes of all degrees, not including 800 deaths from cold. After the four-day battle of Pecaotai in the Russo-Japanese war, there were found to be among the Japanese troops from 1,300 to 1,400 freezes of all degrees, of which 700 to 800 required intervention.

The Italian distinction between perfrigerations and congelations is comparatively new, and is not arbitrary but necessitated by actual conditions. A congelation so called requires, as a rule, a very low temperature, at least $-16^{\circ}\text{C. (+3.2}^{\circ}\text{F.)}$. The sequence of pathological changes is as follows: Ischemia of an intense character; direct coagulation of the blood, lymph, interstitial fluids, etc., and gangrene. A congelation is due entirely to extreme cold while a perfrigeration is due to a lesser degree of cold in association with more or less moisture. One distinction made by the author relates to the type of gangrene produced. In a congelation due to intense cold we see dry gangrene; while moist gangrene can occur under much less severe cold, provided that there is an undue amount of moisture.

It is evident that the congelations include most of the third degree freezes and that ordinarily they are much less common than the perfrigerations. The latter should also show the greatest variety in degree and kind and include so-called trench foot. It is at once apparent that with severe cold, with or without slight moisture, a very different lesion would be caused than when the temperature is relatively low and the exposure to moisture excessive. With congelations there appears to be the greater liability to secondary phenomena like tetanus and sepsis; at least in some figures quoted all complications of this type are set down as present in the severer form of lesion. Perfrigerations are responsible for many sequelæ involving the various tissues of the feet

and legs—ulcers and thickening of the skin, chronic edema, tendinous retraction, osteoporosis, and various types of mutilation.

THE BACTERIOLOGY OF POLIOMYELITIS.

THE work of Dr. Horace Greeley on the bacteriology of poliomyelitis, of which a preliminary announcement was published in the *MEDICAL RECORD* of January 13, 1917, and complete details in the *Journal of Laboratory and Clinical Medicine* in July following, has recently been corroborated by Rosenow* and Bristol.† It will be remembered that Dr. Greeley grew, from the nerve centers of cases succumbing to the 1916 epidemic, a pleomorphic, bipolar bacillus which he caused to grow as the "globoid bodies" described by Flexner and Noguchi and also in the form of the "streptococcus" described by Rosenow. Working with cultures obtained from the latter he developed from Rosenow's "streptococcus" the pleomorphic bacillus. This bacillus, besides being susceptible of modification in form between the globoid bodies, through streptococcus or diplococcus forms, to bipolar bacilli, he found was also subject to change from Gram-positive to Gram-negative. The fully developed bacillus was found to be motile, with a single terminal flagellum, would liquefy solidified serum, produce an acid reaction in neutral bouillon, and develop spores. Five out of six strains isolated by Greeley failed to produce gas in sugar media; three out of the six produced a slight amount of indol. He found that the organism would pass the Berkefeld filter and would grow at all temperatures between summer heat (70° F.) and that of the body. His cultures grew readily in market milk and in it resisted the pasteurization process.

Experimenting on animals Greeley produced paralysis with nerve center lesions in dogs, cats, rabbits, and guinea-pigs, and also typical attacks of distemper in young dogs and cats. A culture accidentally dropped in the experimenter's eye produced an abortive case of the malady, and mucus from his throat produced paralysis in a rabbit and a contagious fatal disease, with nerve center hemorrhagic manifestations among guinea-pigs. He tested the organisms isolated with blood serum from fifty convalescents of the 1916 epidemic and found that, while agglutination was ordinarily not produced in high dilution, a specific relation was evident. In animals (cats) he produced antipoliomyelitis sera that agglutinated in high dilution the cultures used to produce them, but which varied considerably in agglutination of other cultures. Using this specific serum and sera from human poliomyelitis convalescents he showed that a distinct relationship existed between the poliomyelitis bacilli and a bacillus isolated from a case of distemper in a dog.

Rosenow now states that he finds that his strep-

*Rosenow, E. C.: *American Journal of Public Health*, Dec., 1917.

†Bristol, L. D.: *Journal of Medical Research*, Jan., 1918.

tococcus will produce the bacillus form, and Bristol, working with one of Flexner's cultures obtained from the Rockefeller Institute, developed from the globoid bodies bacilli such as Dr. Greeley described. Dr. Bristol concludes: "From these studies I venture to suggest the possibility that the organism of poliomyelitis is a pleomorphic bacillus (often indistinguishable, however, from a true coccus), and that it may be closely related to the large group of so-called bipolar bacilli, or Pasteurella. Based on this assumption, the mode of spread may be considered analogous to that demonstrated for all forms of Pasteurellosis in animals, namely: (1) directly, by contact with the fresh secretions or excretions of an infected individual (either diseased or a healthy 'carrier'); (2) indirectly, by the carriage of the specific organisms by insects, or possibly in dust, uncooked food, or drink."

These are practically the same conclusions as those announced by Dr. Greeley some six months previously.

SPLENECTOMY IN WAR SURGERY.

BEFORE the war most writers admitted the practice of suture of the spleen for wounds of this viscus, but the surgery of war has shown that this treatment is unreliable, not to say dangerous, and in the few cases where it has been resorted to the results have been disastrous. As in the case of suture, packing the wound in the spleen is not always preventive of infection or late hemorrhage. Although not a method of choice, it may be very useful in some few cases in which splenectomy cannot be performed with safety on account of some local or general cause. To be of any use the packing must be tight and should not be removed for at least ten days, otherwise hemorrhage will certainly occur.

The experience gained during the past three years has amply demonstrated that splenectomy is the only proper treatment for wounds of the spleen. It does away with late septic and hemorrhagic complications, and on this point all surgeons, at least in France, are in accord. As to the gravity of removal of the gland, opinions differ somewhat. Willems insists on the circulatory disturbances in his splenectomized patients, but the general sentiment seems to be that the removal of the spleen has no unfortunate ultimate results. This reasoning is justifiable. The brilliant successes of Depage, Kocher, Delore, Fiolle, and others are sufficient evidence of this. At one autoambulance seven splenectomies were done, with five recoveries, the two deaths being due to a duodenal and renal lesion respectively.

The future of patients without a spleen is well known. The blood changes noted after splenectomy are transitory. The red blood corpuscles, at first decreased in numbers, slowly return to the normal, usually within a month. The changes in the white count are equally negligible. All this, however, is theory, and what should be known is whether or not the blood changes are compatible with life. There

is no doubt on this subject. The hypoglobulia following removal of the spleen is temporary and without importance, even when it does occur, and no cases of anemia following the operation have been recorded that could not be explained by the trauma and operation.

Therefore, in neither the immediate nor ultimate consequences of splenectomy need there be reasons for rejecting this operation, which is at the same time radical and sure. It is, of course, not an operation devoid of danger, but if the inconveniences in removal of the gland are compared with the serious dangers inherent to the conservative methods of treatment of splenic wounds in warfare, there can be no hesitation on the surgeon's part.

BUY BONDS

THE third Liberty Loan is offered to-day. Only a little over 10 per cent. of the physicians of the country have given their services to the fighting forces; let the remaining 90 per cent. do their bit by loading up recklessly with bonds. These are as good as gold, pay high interest for an absolutely safe investment, and, best of all, will provide an abundance of men and munitions to wipe the execrable German war machine off the face of the earth.

News of the Week.

Low Death Rate Despite Severe Winter.—Notwithstanding the fact that New York City experienced the coldest weather in its history during the first two months of 1918, the death rate for those months was only 15.51, as against 16.97 for the same period of 1917. If the same death rate had prevailed during January and February of this year as is recorded for those months in 1917 there would have been 2,600 more deaths than actually occurred. The most notable reduction in the mortality was from lobar pneumonia, there having been a decrease of 450 deaths reported from this cause as compared with the corresponding period of 1917. The saving of life has been mostly among adults. The number of births recorded for the first two months of 1918 was 22,021, as against 24,227 during the same period of 1917. There was also a falling off in the number of marriages, 8,389 having occurred in the first two months of this year as compared with 11,187 during the same months of last year.

Children's Bureau Issues Instructions for Weighing and Measuring Test.—The instructions for carrying out the weighing and measuring tests of American children under five years of age have been sent by the Child Welfare Department of the Woman's Committee of the Council of National Defense to its State and local child welfare chairmen, who will be responsible for the test in each community. The record cards will follow after word is received of the exact number required by each committee. These record cards give a table of average heights and weights of boys and girls at birth, at every month of age from the sixth to the forty-eighth, and at every year from the fifth to the sixteenth. One-half of the card will be retained by the parents. It includes the table of heights and

weights and has blanks for subsequent records, so that parents can watch the child's growth. The other half of the card provides for recording the height and weight of the child at the time of the national test. It will be used by the local committee in analyzing the facts about its own community and then it will be forwarded to the Child's Bureau at Washington. This test is the first feature of the Children's Year, which begins on April 6.

The Out-Patient Clinic and Occupational Diseases.—The Executive Committee of the Associated Out-Patient Clinics of New York City calls attention to the fact that there exists a great deal of occupational disease, and that cases of occupational disease are often not properly diagnosed in the out-patient clinics. In order to provide the sick with competent medical advice, resolutions have been passed calling the attention of the boards of trustees of dispensaries situated in industrial sections of the city to the need of early recognition of occupational disease, and stating that in order to facilitate the work of the physicians in this task detailed records should be taken as to the occupation of all patients. These resolutions also require that adequate facilities be provided for the treatment of occupational diseases and industrial poisonings, and that an interest in the study of occupational diseases should be stimulated among physicians connected with the dispensaries.

Smallpox on Sound Liner.—Five negro employees of the Hartford Line steamer *Middletown*, which makes regular trips between New York, Hartford, and intermediate landings, were taken to the Kingston Avenue Hospital, Brooklyn, on March 29, suffering from smallpox. The *Middletown* usually carries from 130 to 150 passengers on each trip. The Health Department of New York City is endeavoring to reach all of these passengers with the warning that they should be vaccinated immediately.

Memorial to Dr. David Williams Cheever.—A large bronze memorial bas-relief of Dr. David Williams Cheever was unveiled in the amphitheater of the Boston City Hospital on March 21. In addition to his many other professional activities Dr. Cheever established the first surgical clinics in the Boston City Hospital, and carried them on throughout his life, having given instruction to thirty-three classes of students. The tablet was presented by Dr. David Cheever, who reviewed the part his father played in the life of the Boston City Hospital. Dr. George W. Gay presided at the ceremonies, which were attended by a number of Dr. Cheever's contemporaries.

Bill to Close Medical School.—A bill is pending before the Legislature of Massachusetts which would withdraw from the College of Physicians and Surgeons of Boston its power to grant medical degrees. At a recent hearing on the bill before the legislative committee on education more than one hundred opponents of the proposed legislation appeared and protested against its passage.

Studying Effect of Pneumatic Hammers on Workers' Health.—The United States Public Health Service has begun a study of the effect on the health of workers of pneumatic hammers, as used in cutting limestone. It has been learned that inconvenience is felt by workers in this industry

in using the air hammers in soft stone because of a temporary numbness of the fingers whenever the hand becomes chilled. The cause of this was found to be the higher vibration rate of the hammers when used in soft stone, and a second cause was the tight and strained grasp which the workers had to use. It was found that using a shank of larger diameter with a tight-fitting cover of asbestos made a more comfortable grasp possible, and the asbestos acted as a shock absorber.

Hungary's Decreasing Birth Rate.—A statistical report read before the Hungarian Chamber of Deputies at the session of January 16, 1918, states that before the war 765,000 children a year were born in Hungary. During the first year of the war the number of births was reduced by 18,000; in 1915 only 481,000 children were born; in 1916 the number of births was 333,000; in 1917 the births amounted to 328,000. This would represent a loss of 1,172,866 individuals, or a 50 per cent. decrease in the birth rate. In times of peace the infant mortality for a period of seven years was 43 per cent.; in 1915 the proportion was increased to 48 per cent., and in 1916 to 50 per cent.

Laboratory Test for War-Time Recipes.—An experimental laboratory has been established in which representatives of the Food Administration will cooperate with those of the Department of Agriculture in standardizing war-time recipes and putting them out in the form in which they will be most useful. Recipes will be tried and their nutritive values thoroughly tested.

The Sacramento Society for Medical Improvement celebrated the fiftieth anniversary of its organization on March 16. Dr. W. R. Cluness, the only surviving organizer, presided at the banquet. The society has elected Dr. George A. Briggs *President*, and Dr. W. A. Beattie *Secretary-Treasurer* for the ensuing year.

The Newport County Medical Society, at its annual meeting, on March 22, elected the following officers: *President*, Dr. Edward V. Murphy; *First Vice-President*, Dr. A. F. Squire; *Second Vice-President*, Dr. Charles W. Stewart; *Secretary*, Dr. A. Chace Sanford; *Treasurer*, Dr. P. A. Jacoby.

Hearing on Health Insurance.—The Nicholl bill, a measure providing for workmen's health insurance, is before the Legislature of New York State. The bill was drawn by the American Association for Labor Legislation. A hearing on this bill was held on March 26.

United States Public Health Service Testing Vaccines and Serums.—Samples from every lot of serums and vaccines made by the various manufacturers are now being tested by the United States Public Health Service at the hygienic laboratory in Washington, before the products are placed on the market for interstate traffic. As rapidly as possible the Public Health Service has been determining upon standards for the different serums and vaccines, and where sufficiently accurate standards can be found manufacturers are held up to them. Tests for reliability are now made in the serums and vaccines of pneumonia, meningitis, smallpox, typhoid fever, diphtheria, and tetanus. At the present time a large number of firms are licensed for the manufacture of these products, this meaning that the establishments are satisfactory from a

sanitary point of view and that their products are free from contamination.

Health Department Proposes Ordinance to Cut Food Waste.—The Health Commissioner of New York City, Dr. J. Lewis Amster, has submitted to the Welfare Committee of the Board of Aldermen an ordinance setting a penalty of ten days' imprisonment or \$50 fine for the offense of wasting food. The Health Commissioner has been checking up the amount of food wasted in the city during the past year, and finds that enough has been thrown away to feed 136,000 people, and its value is estimated at \$16,000,000. He finds that the worst waste is through servants in the homes of the well to do, and estimates that in bread alone as much as 6,000,000 pounds a year have been thrown away.

Gifts and Bequests.—Under the will of Mrs. Elizabeth C. Farnham a bequest of \$12,000 is made to Harvard University to create two medical scholarships in the medical school.

Dr. Kristine Mann, director of the health clinic for industrial women in New York City, and lecturer on hygiene at Smith College, has been appointed head of the Health Department in the Women's Division of the Industrial Section Service of the Ordnance Department of the Army, which has been created to look after the health of women employed in the arsenals and other ordnance plants. It is planned to train health officers for the needs of industry. Dr. Mann has asked one of the women's colleges to establish a summer course for women equipped to qualify for this, which would include anatomy, physiology and sociology.

Obituary Notes.—Dr. WILLIAM OGDEN McDONALD died at his home in New York City on March 25, aged 82 years. He was graduated from the New York Medical College in 1855, served as a surgeon during the Civil War, retiring with the rank of lieutenant colonel, was a pension examiner from 1877 to 1884, and later professor of anatomy and gynecology in the New York Homeopathic Medical College.

Dr. ALBERT MEHRER MOORE died of cerebrospinal meningitis, at Philadelphia, on March 6, at the age of 42 years. He was graduated from the Medico-Chirurgical College in the class of 1905, and he had been an instructor in anatomy in his alma mater for ten years.

Dr. JOHN S. TRYON died at Rehrersburg, Pa., on March 6, at the age of 84 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1857.

Dr. WM. HENRY MCCURDY died of pneumonia at Delta, Pa., on March 21, at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1881. He was chairman of York County Draft Board No. 2.

Dr. C. FRANK OSMAN, a graduate of the Harvard Medical School, in 1880, died at his home in Dorchester, Mass., on March 9, aged 62 years.

Dr. JOHN W. SPEER of Alton, Ky., a graduate of the Miami Medical College, Cincinnati, in 1867, died in a hospital in Frankfort, Ky., on March 5, aged 82 years.

Dr. BENJAMIN P. WILSON of Lake Butler, Fla., a graduate of Charity Hospital Medical College in 1876, died in Snead, Fla., on March 10, aged 66 years.

Dr. RANSFORD DELOS CANEDY of North Adams, Mass., who has served several terms on the Board of Health of that city, died, after a brief illness, on March 10, aged 45 years.

Dr. CLARENCE L. HOWES, a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1878, died at his home in Brockton, Mass., on March 7, aged 70 years.

Dr. JOHN W. ROBERTS, a graduate of the Fort Worth School of Medicine, in 1910, died at his home in Irving, Texas, after an illness of several months, on March 8, aged 34 years.

Dr. GEORGE E. HALLEY died at his home in Kansas City on March 11, aged 78 years. He was a graduate of the Victoria University Medical Department, Canada, and was formerly professor of the principles and practice of surgery in the Kansas City Medical College, and later of the University Medical College.

Dr. RALPH E. MOESSER of Montrose, Ill., was killed in an automobile accident on March 8. He was a graduate of the Kansas City Hahnemann Medical College in 1910, and was 33 years of age at the time of his death.

Dr. SARAH R. ELLISON, retired, a graduate of McGill University, in 1873, died at his home in New York City, on March 25.

Dr. JOHN AUGUST WALTHER of New York, a graduate of the College of Physicians and Surgeons, New York, in 1876, died suddenly at the Memorial Hospital on March 27.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

A MINISTRY OF HEALTH—INVALIDS AND FOOD RATIONING—TWILIGHT SLEEP—DISCHARGED SAILORS AND SOLDIERS AS DENTAL MECHANICS—THE MEDICAL STUDENT AND COMPULSORY MILITARY SERVICE—A MEDICAL PARLIAMENTARIAN—DEATH OF DR. FLEMING MANT SANDWICH.

LONDON, March 14, 1918.

THE country has now been promised, and promised definitely for over six months, that it is the intention of the government to bring in a bill creating a Ministry of Health, the new bureau taking its place as a first-class government department, with its head occupying a seat in the Cabinet. At the present moment the health of the country, so far as it is not in the hands of individual practitioners, is a charge upon half a dozen public bodies. Mainly, it is true, the responsibility devolves upon the local government board, the authority for all public sanitary work, notification of disease, arrangement of sewerage schemes, and so on; but the parts played by the Home Office and the statistical records of Somerset House, by the Foreign Office, and even the Privy Council, are significant, while the commissioners under the National Insurance Act, who trol the whole of panel practice—that is to say the medical care of 14,000,000 out of 36,000,000 persons—have a most practical interest in every conceivable question of national health. The bill is to collate, arrange, and coordinate all these activities, and ought to have made its advent in the House of Commons ere this, while the delay is usually explained

by the difficulty of getting universal agreement upon the fundamental point of the direction in which the supreme authority shall be conferred. To make the Health Ministry a new and separate entity is tempting, but it means the scrapping of many admirable organizations and replacing them in a hurry, to say nothing of eternal overlapping with the functions of the Local Government Board. To erect the medical branch of the Local Government Board into a first-class bureau is the obvious alternative, and one that will probably be followed, but the powers and discretions wielded by the Commissioners of the National Insurance Act cannot be curtailed to a point at which any medical department of the Local Government Board would really be in supreme authority without a struggle. In the meantime the country awaits with impatience the creation of the new Health Ministry for the solution of many important questions. For example, infantile mortality, which in the first three years of the war showed at one time a magnificent decline and at other times a rate below the decennial normal, now exhibits a tendency to rise, and stricter measures of notification are being called for. But the National Health Commission dislikes a system of notification of pregnancy along the usual lines, because this would mean the intervention in domiciliary medical practice of the medical officer of health, who is an officer of the Local Government Board, with functions directed toward the maintenance of public health. The expectant public and medical profession have begun to surmise that so long as these powerful opposing interests are allowed free play so long will last the delay of the bill to create a Ministry of Health; but this week Mr. Bonar Law, the chancellor of the exchequer, announced in the House of Commons that a bill dealing with the incidence of infantile mortality is to be brought forward immediately, the measure not affecting in any way the larger portion of a Ministry of Health.

In addition to the regulations which I reported to you last week it has been decided that for the time being extra allowances of butter and margarine will be sanctioned only for invalids suffering from glycosuria, tuberculosis, celiac disease, or pancreatic insufficiency.

Not long ago a special committee appointed by the Obstetrical Section of the Royal Society of Medicine reported upon scopolamine narcosis in childbirth, in a careful and upon the whole not a condemnatory sense. But the medical profession in Great Britain were already confirmed in a general if vague district of a technique which, though it had received large support in good places in America, was of German origin, and relied for much of its good character upon opinions uttered by German eulogists. To some extent, however, the public has its medical treatment in its own hands, and many members of the public, believing that in "twilight sleep" there may be an easy and safe escape from the pangs of childbirth, insisted upon trials being made of the method. Tragedies have not followed, nor does the oligopnea appear to have been prejudicial to the infants, and in consequence medical practitioners have been more and more pressed by their clients to absorb this technique.

A debate this week before the Clinical Society upon the advantages and disadvantages attending

twilight sleep was consequently very timely, but in the result matters remain where they were. Dr. G. F. Blacker, obstetric physician to University College Hospital; Dr. Herbert Spencer, consulting obstetrician to the same institution, and Dr. Amand Routh, obstetric physician to Charing Cross Hospital, all spoke in a critical spirit. The first named, who initiated the debate, summarized the results recorded by various observers, as well as the report of the committee of the obstetrical section of the Royal Society of Medicine, and in dwelling upon such drawbacks as he enumerated admitted that he did this rather insistently because the public impression was that the method was accompanied by no dangers to mother or child. Dr. Routh, while allowing that twilight sleep had proved useful in the case of nervous and timid women, referred to the very ill consequences of a prolongation of the second state of labor and of uterine inertia. Dr. Spencer denounced the whole technique as perilous, and deceptive in that it promised to the mother benefits that it could not confer, and ridiculed in detail the statistical statements recently emanating from Freiburg. The question is not likely to rest here, as there are many practitioners in England who have experience of what they consider to be the good results achieved by twilight sleep in those nursing homes which make a specialty of this treatment of labor cases. Facts and figures will be brought forward in the near future, probably, from such centers of close observation, supporting some at least of the claims of those who practise the method; but such advocacy, it will be seen, points to a distinct revolution in English medical practice, for it will signify that the right place for a woman to be delivered is in an institution, and not in her own home.

A scheme for the training of discharged sailors and soldiers in dental mechanics has now been approved, and is in actual working in London, Manchester, Newcastle, and Swansea, while it is just coming into operation in Liverpool. None know better than these men how severely the systematic neglect of the teeth has told on (to say the least) the comfort of the British navy and army.

With conscription, the medical student ceased to exist, but already before the first year of the war had gone by, he had become a very rare individual, for his patriotism had taken him voluntarily into the ranks. At the time, warnings were raised by the General Medical Council, or the central body of medical education, by many individual teachers, by the *Lancet*, and by a certain number of parents whose boys had stopped short in their careers. All the warnings had the same message—namely, that a doctor, always a valuable citizen, bade fair to become a most precious object to the State; that it took five uninterrupted years of study to educate him; and that to direct some thousands of these young men from the career in which they had embarked was to cause an inevitable shortage in the medical profession in years to come—and this for the sake of adding to an immense army what, in relation to the massed figures, was only a handful of recruits. Concessions to this way of feeling were made promptly, in that senior students were allowed to resign their commission or retire from the ranks on the understanding that they returned to

their studies, and justified the privilege by proceeding to get qualified immediately, when they would, of course, be available for commission in the navy or army medical services, which were drawing on the depleted numbers of the civilian medical profession.

Under the latest National Service Instruction, which was issued in the latter half of March only, medical study at last becomes "a reserved subject" (i.e. a pursuit which exempts its followers from conscription) as prudent people said three years ago that it should be. Provided that a medical student has passed his first professional examination in chemistry, physics, and biology, shows reasonable diligence in passing the later examinations, and joins an Officers' Training Corps he will now not be called up for service, military or naval. The reference is actually also to students who have not yet passed the first professional examination, but who succeed in doing so in the coming summer tests; while all medical students whose classification under physical tests for recruiting comes low in the category are exempted. The position of every medical student in the country will be reviewed now, and again in six months' time.

Few medical men have been members of the British Parliament, fewer have made any mark there, and where they have raised themselves from the ruck their advance has been due to political efficiency and not to scientific reputation or achievement. At the close of the last century Sir Walter Foster, a provincial physician, became a minister and a peer, but entirely as a reward for services in party politics; simultaneously Sir Michael Foster, secretary of the Royal Society, one of the greatest British physiologists and representative of an important university constituency, failed to make any real impression upon his fellow legislators. In the present British government there are two men with the right to style themselves physicians, namely Sir Auckland Geddes, Director of Recruiting, and lately professor of anatomy in Montreal, and Dr. Christopher Addison, Minister of Reconstruction, and formerly lecturer on anatomy at St. Bartholomew's Hospital, London. Both of these are of real consequence to the country in their important posts, but the consequence lies entirely outside their scientific attainments. But the British House of Commons now contains a distinguished medical man, who has been accepted as a leader in its deliberations because he is a medical man, namely Sir Watson Cheyne, member for the University of Edinburgh and formerly president of the Royal College of Surgeons of England. Sir Watson Cheyne is a quiet, fearless, sensible speaker, and on two notable occasions has intervened in debate with marked success when stating the medical view. On the first occasion the House of Commons was discussing the granting of commissions in the army as medical men to certain unqualified persons, stated by grateful patients to be endowed with extraordinary medical skill. The House, many members of which had been no doubt approached on behalf of one or two of the best known of these unqualified practitioners, appeared to be willing to take the easy step of conceding to unscientific opinion, when Sir Watson Cheyne, then quite a new member, put the whole affair from the

scientific aspect, pointing out the enormous dangers that must be run by the army if the safeguards of medical standardization and qualification were removed for those who attended the sick and wounded soldiers. Sir Watson Cheyne's second notable intervention in debate occurred during the discussion upon the constitution of a special medical service for the British Air Force. Chairman of the committee which had drawn up a scheme for the creation of such a service, and which by its clear-speaking had brought about official recognition of the urgent physical and mental needs of the flying man, he delivered to the House of Commons what was nothing less than a clinical lecture on the effect of varying barometric pressures, thermometric altitudes, oxygen starvation, and nervous strain upon the human organization. He was listened to with the deepest attention, and his words are likely to have the valuable result that the new service, whose existing pattern is not wholly satisfactory, will be allowed to develop along lines free from any interference from other services, so that it will attract the very best material from the newly qualified medical men.

The death has occurred very suddenly in his sixty-fifth year of Dr. Fleming Mant Sandwith, a well-known authority on tropical diseases and a vigorous worker in behalf of the Red Cross. His association with military ambulance work dated from forty years ago, for in 1877 and the following years he served as surgeon to the National Aid Society's Ambulance in the Turko-Serbian War and to the Stafford House Ambulance in the Russo-Turkish War. He was for a time Vice-Director of the Egyptian Public Health Department and professor of medicine at the Cairo Medical School, on resigning which posts he was appointed Gresham Professor of Medicine in London. During the South African War he acted as physician to the Imperial Yeomanry Hospital, and at the time of his death he was consulting physician to the East Mediterranean Force. Truly a life spent in public service.

3. Observations on Disabled Shoulders.—Hilbert F. Day points out that in practically all cases of shoulder disability a history of trauma can be obtained. There is usually soreness which may subside and then develop into persistent and often very acute pain in the shoulder, accompanied by limitation of motion. An x-ray picture should be taken to clear up the diagnosis. Most of the cases that have come under Day's observation have been seen several days or weeks after the initial injury. The diagnoses of injuries have appeared in the following order: (1) Sub-acromial bursitis, (a) without further injury, (b) with tear of the supraspinatus tendon, (c) with calcareous deposit. (2) Injury of the supraspinatus tendon alone, which is probably caused by pressure on the sharp under edge of the acromion on the tendon, made during sudden, violent motion of the arm. (3) Fracture of the greater tuberosity of the

humerus. (4) Loose joint capsule causing some subluxation of the humerus. (5) Traumatic periostitis. (6) Disease of the head of the humerus, as syphilis, tuberculosis or neoplasm. (7) Brachial neuritis. The greatest number of cases were included under the sub-acromial bursitis group. The author states that *anatomically* the subacromial bursa embraces what is often spoken of as the subdeltoid bursa and that the latter division disappears when the arm is abducted; it is simply that portion of the subacromial bursa which lies under the deltoid muscle beyond the acromion process when the arm is adducted. The bursa is $2\frac{1}{2}$ to 3 inches in diameter. Its under surface is firmly attached to the tuberosity of the humerus and to the expansion of the supraspinatus tendon. Its upper surface is attached to the under surface of the acromion and coraco-acromial ligament, and to the under fibers of the deltoid muscle. With the arm adducted, the subdeltoid portion of the bursa is exposed to trauma. When the supraspinatus tendon is injured or lacerated, full abduction is impossible. The chief function of the deltoid muscle is to hold the head of the humerus firmly under the acromion and in the glenoid cavity. Day states that practically all cases of subacromial bursitis that have been under his observation long enough have recovered "despite treatment or the absence of it." In untreated cases the symptoms vary from six months to three years. A few patients who were willing to carry out ideal treatment recovered in two months. *Treatment*: In acute cases aspirin should be given for the pain and the patient should be put to bed in a semi-recumbent position, the affected arm abducted on a pillow and a muslin bandage lightly looped around the wrist and attached to the headpiece of the bed; or, as suggested by Codman, a splint may be bound to the back of the forearm and a cord run from either end of it to the head of the bed. The upper end of the bed is then raised and as the patient's body slides gradually down, the arm is drawn further and further up, and thus a shoulder that resists forcible efforts at abduction yields painlessly to a gradual countertraction. Immediate operation is advisable in cases of partial rupture of the supraspinatus tendon or in cases where adhesions have formed in the bursa. Subacute cases may be treated (a) by an operation, with the object of separating adhesions, and, if necessary, removing the bursal floor; (b) by forcible breaking up of adhesions with manipulations, the patient being anesthetized; (c) by gradual stretching, as is accomplished by nature without treatment, or more rapid gradual stretching by massage, passive motion, Zander treatment or active exercises. The treatment of chronic cases requires both patience and time. Baking and massage should be given at regular intervals, generally every other day, and should be followed by graded exercises which should be taken preferably at night, so that they may be succeeded by rest. The author believes that trauma is an essential cause of sub-acromial bursitis and that the condition is not caused by infection; secondary infection, however, may keep up the inflammation.

7. Dead Teeth. Josef Novitzky.

7. Dead Teeth.—Josef Novitzky defines any tooth whose pulp supply has been cut off as a dead tooth. He states that the various methods and medicaments employed to sterilize the dentine of a dead tooth serve merely to retard, and do not prevent decomposition. Root amputations, and the transplanting, replanting and implanting of teeth all fail as attempts to retain a dead tooth in the jaw with security against ill results. No matter whether extracted teeth are sewn into a cock's comb until needed or boiled before plantation, the roots of implanted teeth are absorbed. The primary and secondary lesions resulting from the retention of dead teeth in the jaws are well recognized, but two main points should be emphasized: (1) A microorganism, a poisonous protein, or a toxin introduced into the blood-

stream by way of cancellous bone would be more active than would be the same amount of it introduced into the stomach. (2) If it is introduced into the bloodstream in small amounts over a long period it may break down the body resistance. On account of ills resulting from the retention of dead teeth in the jaws and on account of the impossibility of rendering dead teeth permanently aseptic, it must be concluded that teeth should not be devitalized. In most cases in which exposed nerves were "killed" it would have been possible to retain the pulp alive by covering it with a zinc oxide creosote paste. The teeth, however, should not be "pulled," but should be dissected out according to a technic described by the author as follows: Under local anesthesia the gums and the periosteum may be cut loose and retracted along the entire side of the jaw if this is necessary in order to gain space for operating. If the gums are carefully sutured back in normal position against the teeth, reattachment will take place. Ordinarily it is sufficient to cut a triangular flap with the apex pointing to the gingival margin of the tooth to be removed. This flap is raised and held back. The buccal or labial wall of bone over the entire root length of the involved tooth or enough to give direct access to the apical region is removed with the chisel. The removal of the bone over the entire root length allows the roots to be used as a guide to apical pathology. Drainage points, no matter how minute they may be, are plainly seen. If bone is removed over only part of the root length, the tooth must be removed, of course, before the apical curettement can be done. The tooth may be hooked out sidewise either before or after the apical exploration and curettement, depending on whether or not the entire root length of the buccal plate has been removed. The external periosteum flap is pulled into the opening at completion of the operation with a suture. The removal of bone over the entire root length allows the falling in of the periosteal flap and rapid healing. Gauze packings are usually avoided. Novitzky states the advantages of this technic to be: (1) It avoids fractures which commonly result from attempts to "pull" ankylosed teeth. Dead teeth are usually partially ankylosed and very brittle. (2) It gives opportunity for complete curettement on account of the direct access to the affected parts. (3) It avoids the retention of septic bone and granulations which may result in systemic toxemias or bacteriemias. Infective thrombosis or embolism is particularly apt to follow the opening of facial veins. (4) It renders apparent any pathologic involvement of the nasal floor and any vents under the antral membrane or into the nasopalatine canals or into the dental canal of the mandible. (5) It avoids the low grade suppuration due to incomplete surgery, which causes extensive absorption of the alveolar process. The loss of bone on account of such absorption destroys the foundation necessary for an efficient plate.

2. The Principle of Treatment in Mercuric Chloride Poisoning: An Experimental Study.—W. D. Sansum found that the minimum uniformly lethal dose of mercuric chloride in dogs was 4 mg. per kilogram of body weight (1:1000 solution injected uniformly during from fifteen to sixty minutes). This corresponds approxi-

mately to the smallest doses of mercuric chloride known to cause death in man. A dose of 5 mg. per kilogram was found necessary to produce anuria. In cases of anuria thus produced, all attempts to reestablish the flow of urine by intravenous administrations of strongly diuretic solutions failed. In animals which had received the minimum uniformly lethal dose of mercuric chloride, but in which the kidneys were still capable of functioning actively, efforts to save the dogs by copious systemic lavage by means of intravenous injections of highly diuretic sugar or salt and alkali solutions met with no success, and in fact usually shortened life. Intravenous injections of sodium acetate-sodium phosphate solutions were likewise of no value even when given immediately after the mercuric chloride and when the weights of sodium phosphite were from twenty to thirty-five times as great as the weights of the mercuric chloride administered. Dogs and rabbits that had received by vein the minimum uniformly lethal dose of mercuric chloride died in spite of the use of the best known forms of alimentary medication. Sansum draws the following conclusions: (1) There is no sound experimental basis for the belief that the promotion of free diuresis contributes materially to the chances of recovery in mercuric chloride poisoning, and this phase of treatment should not be permitted to obscure that which is more essential. (2) Combined treatments which involve sweating, diuresis and increased elimination from the bowel probably owe their value chiefly to the latter effort. (3) It would appear in the light of the present study that when 4 mg. or more of mercuric chloride per kilogram of body weight has entered the tissues at large, death regularly occurs, and that we have no adequate grounds for believing that death is preventable by any known form of treatment. Whereas, subsequent studies may add to our knowledge, it would appear that persons who have recovered from mercuric chloride poisoning owe their lives to the fact that a lethal dose has never gained access to the extraportal circulation. Practical therapeutic efforts should be directed frankly toward the accomplishment of two things: (a) Mechanical removal of the poison from the lumen of the alimentary tract; (b) antidoting the poison before it leaves the portal circuit, that is, particularly before absorption.

3. Eye-strain: The Condition of Blepsopathia.—Harold A. Des Voeux, from an analysis of 100 cases, including 35 males and 65 females, gives the following as the syndrome produced by eye-strain: fears and panics; depression of spirits and vitality; fits or attacks (including fainting); giddiness, dizziness and vertigo; fatigue; indigestion; disorders of sleep; train vomiting. If the surrounding conditions are favorable to their production the symptoms show themselves in a minor degree in childhood, and become quite manifest at about the age of 15 to 25. The greatest success in treatment is attained at this age. Whatever the actual cause of pain, the author states there can be little doubt that it is some physical alteration in the nerve cells, and that as years go on this alteration tends to become permanent and incurable. The general health of patients is often good and there is complete absence of true symptoms or signs of disease or disturbance of the liver. Some patients suffer from colitis, but in most cases the eye-strain preceded this disease. Heart disease is conspicuous by its absence. Des Voeux points out that it is the slight degrees of error of accommodation that do the harm, not the extreme degrees. In some cases the orbits of the eyes are not horizontal and in young patients twitching of the lower lid is very pathognomonic. His studies have been conducted from first hand observation only, unaided and unbiased by the writings of others, and he has reached the following conclusions:

(1) Eye-strain is very common among brain workers and town dwellers. (2) It is produced especially by the minor degrees of refraction. (3) It is uncommon with the higher degrees because the less a man can see the less he strains. (4) It is the quick, intelligent, educated eye that suffers. (5) Eye-strain leads by slow degrees to definite nervous symptoms and breakdown—a condition which he calls blepsopathia. (6) The disease shows its first signs in childhood or youth. (7) It is easily cured in youth, with more difficulty in older age. (8) It is useless to pay attention to the patient's report on his own eyesight.

4. General Analgesia by Oral Administration.—Captains James T. Gwathmey and Howard T. Karsner state that the present report is in the nature of a preliminary communication based on animal experiments and a sufficient number of clinical cases to support the conclusions of the animal work. They found that general analgesia in which there is loss of sensation, with or without loss of consciousness, could be established for otherwise painful dressings or short operations, and they refer to the great value of such a procedure in military hospitals, particularly as it is not necessary to move the patient from his bed. These authors proved by means of experiments on rabbits that analgesia could be produced by the oral administration of proper agents. The best results were obtained by ether in olive oil, but its administration produced acute gastritis in these animals. It was found that olive oil alone also produced this condition. As olive oil is non-irritant to the human stomach, the investigations were proceeded with on man. It was thought, however, that some mineral oils might be less irritant and, accordingly, the menstruum was changed to liquid paraffin (albolene), or Russian mineral oil. Finally a 65 per cent. solution of ether in oil was used in many thousands of cases of oil ether colonic anesthesia without any sign of local irritation to rectum or colon. The authors point out that the physiology of "general anesthesia" by oral administration has not been subjected to an exhaustive investigation, but certain important facts should be borne in mind by those who contemplate using the method. The oil and ether mix perfectly, and do not separate into layers. Baskerville has shown the rate of evaporation from minute to minute to be constant, so as to form a straight oblique line when plotted out. This holds true with different percentages of ether in the oil, assuming a constant temperature and exposed surface, so that it is impossible for the patient to get either an overdose or an underdose. As the total amount is not absorbed at one time, a light analgesia is obtained which, for operative procedures, must usually be supplemented in some way. The surface for evaporation is greater in the stomach than in the case in the colonic method, and the absorption of ether more rapid. The total amount that may be given with safety by this method has not yet been determined. It is considered advisable for the present to supplement the method by local anesthesia or the administration of small amounts of anesthetic by inhalation. The safety of the method is apparent if it is remembered that a patient in the analgesic stage is separated from the

danger zone by the period of anesthesia. If the anesthetist, however, carries his patient to the "blear-eyed," snoring stage, he defeats the object for which this method was devised. If adopted, the method would release from the routine of administration of anesthetics a certain number of physicians who now, in military hospitals, devote their entire time to that work. It is felt that so far as one can do so in a preliminary communication of this sort, the following conclusions are justified: (1) General analgesia is safer than general anesthesia. (2) Fifty per cent. ether in liquid paraffin, or other bland oil, is probably the safest general analgesic, has apparently no deleterious effect upon the stomach, and is not followed by the nausea and vomiting that frequently accompany inhalation anesthesia. Its effect may be enhanced by the addition of a small amount of chloroform (fl5 ss to j). It may be given without unpleasant taste when "sandwiched" between mouthfuls of port wine. (3) The method is especially indicated during the dressing of painful wounds without taking the patient from his bed or ward, and, when supplemented, can be employed for surgical operations.

Berliner klinische Wochenschrift.

January 7, 1918.

This number is taken up with the proceedings of the Berlin Medical Society of December 5 and 12, 1917, during which meetings the question of medical interruption of pregnancy was discussed.

Bumm points out the modern tendency to enlarge the indications of induced abortion. The medical indications have still more been reinforced by social and economic consideration, without speaking of the pressure brought to bear on the medical man by the patient's relatives when pregnancies are too frequent. Bumm himself has witnessed a large number of patients pass through his clinic and nevertheless only fifty-nine induced abortions have been performed there in the lapse of five years. If the other Berlin gynecological clinics have produced ten times that number of induced abortions this total of some 132 cases per year only represents 1/100 per cent. of yearly abortions in the city of Berlin, if one can be guided by an approximate estimate. Bumm then offers the following figures as probably being near the reality: (A) Natural loss: Deficit from family sterility, 220,000 children; abortion following disease and fortuitous accidents, 55,000 children; dead born, of which 9,000 are due to syphilis, 9,000 to nephritis, mechanical or other disturbances during labor, 36,000 children, giving a total of 475,000. (B) Artificial loss: Mortality at the rate of 40 births per 1,000 inhabitants, therefore for 68,000,000 inhabitants of the German Empire, 2,720,000 births; actual number of births in 1914, 1,818,596 births, giving a deficit of 901,404 births, of which 800,000 are due to preventive measures against fecundation and 100,000 are due to induced abortion. The reason for this condition of affairs is due to a change in ethical ideas, and it is from this standpoint that a campaign should be made.

Münchener medizinische Wochenschrift.

January 8, 1918.

The Treatment of Pulmonary Tuberculosis with Partial Isolated Antigens and a Mixture of Partial Antigens.—W. Müller points out that subjects with pulmonary tuberculosis offer a decided decrease in lipolytic antibodies, but that on the other hand the antibodies reacting against the albumins of the tubercle bacillus are rather increased than otherwise. In opposition to Deycke-Iluch, who looks upon this as a nefarious phenomenon for the patient, Müller explains its occurrence by a change taking place in the specific bacillus under the influence of a defensive reaction of the organism, the change consisting in a decrease of the antigens of the lipid series. The question to be solved is whether or not the cases are to be treated with partial antigens or by a mixture of antigens, just as they are realized the residue of fractional extraction. Having experimented with both treatments, Müller concludes that the injection of bacterial residues containing the lipid antigens, the fatty antigens, and

the albumin antigens has more effect than the injection of lipoid antigen alone. He also produces a more marked reactivity of the organism against the fatty antigens. This fact the writer explains by the changes that the manipulations of extraction impose upon the antigens. However, Müller concludes that an exclusive treatment by these specific methods is inferior to a mixed treatment which is quite equal to radiotherapy.

Cutaneous Cicatrices Following Bullet Wounds; Their Sequelæ and Treatment.—A. Schoenbank remarks that the sequelæ to be feared are limitation of movement and ulcerative processes due to the effect of traction exercised by the muscles adherent to the cicatrix. Operative treatment alone is capable of correcting the disturbances observed. The skin must be separated from the underlying structures, the cicatricial tissue in the superficial aponeurosis excised (a small cutaneous cicatrix may be left alone), and the muscles covered by healthy aponeuroses. A secondary cutaneous suture is done several days later if the wound is free from suppuration. Secondary suture of the integuments is recommended on account of the great tendency to the formation of hematomata. If cicatricial tissue has to be excised from the muscles the latter should be sutured in order to avoid muscular cavities.

Deutsche medizinische Wochenschrift.

January 10, 1918.

The Treatment of Tuberculosis of the Lymphnodes in the Adult.—Mühlmann refers to the treatment by radiotherapy, which offers many advantages over operative treatment. Many persons will submit to radium treatment, but not to operative treatment, on account of the resulting scars, as well as certain sequelæ, such as fistulæ, cutaneous infections, or an extension of the process, as well as possible injury to the spinal nerve, an accident that the writer has thrice met with. Basing his remarks on his favorable results, the writer comes to the conclusion that tuberculous lymphnodes which have become caseous should not be removed by the knife, likewise those offering inflammatory phenomena. These should be treated by radium and only lymphnodes having a hyperplastic tendency should be operated on.

Should Patients Presenting Genital Ulcerations of a Doubtful Nature Be Placed Upon a Prophylactic Antisyphilitic Treatment?—Stürmer replies in the affirmative to this question, based upon the following considerations: The first period of luetic infection is the most favorable for abortive treatment, and when possible should be resorted to before a positive Wassermann is obtained. The risk of treating a nonsyphilitic venereal subject is less great than that of neglecting an early syphilis. In point of fact, Stürmer believes it possible to abort a syphilis in the beginning, whereas waiting, in order to make a positive diagnosis, exposes the patient to a treatment requiring several years, and which is often not properly carried out. It is bad practice to commence treatment with Hg., as this drug has an absolutely sterilizing action in regard to salvarsan. Patients treated early in their luetic process with salvarsan present a "spirochete fever," which is absent when they have first been treated with Hg. This fever corresponds to a "brutal destruction" of the parasites. The writer thought treatment with salvarsan should be immediately commenced in all cases of doubtful ulceration of the genitalia.

Wiener medizinische Wochenschrift.

January 12, 1918.

Post-Operative Treatment.—H. S. Spitzzy draws general conclusions from a personal experience of 18,000 cases. The larger number of cases are those of contractures, then come amputations, paralyses, and lastly shortening of limbs, etc. In spite of the intricate lesions offered by these different categories of cases, and the coexistence of several of these conditions in the same patient, Spitzzy has found it advantageous to specialize his medical and hospital personnel in the treatment of any one of these types. He even goes so far as to sort out the limbs involved and to group

them in wards by themselves. At the beginning the writer was hindered from the want of medical men possessing sufficient orthopedic knowledge so that he was obliged to remedy this condition of affairs by a course on the subject. However, even at present it would be a good thing to have consulting specialists, as exist in Germany, attached to each army corps. Passing to more special conditions, Spitzzy reviews the various surgical means for treating deformities, ankyloses, contractures, etc. He points out the utility of embedding the tendons in fat likewise in cases of musculo-osseous and aponeurotic adhesions. He is a partisan of primary suture in nerve injuries.

Experiences in Ophthalmology of Warfare.—A. Hönig has met with gonorrheal ophthalmia with relative frequency. This evidently is due to the multiplication of venereal disease in general, contamination usually being carried out by the patient himself. Hönig treated these cases by intraglutal milk injections (according to Müller's procedure). The results, although not demonstrating this treatment to be a specific of gonorrheal ophthalmia, have nevertheless proven the utility of this therapeutic measure, which is a useful adjuvant to local treatment. The same treatment used in two cases of iritis and one case of corneal abscess were crowned by success. There was a negative result in three other cases, one each of corneal ulcer, lacryocystitis, and trachoma.

El Siglo Médico.

January 10, 1918.

On a Focus of Endemic Goiter and Cretinism in the Province of Avila.—Goyanes refers to the incidence of these affections in two valleys in this province, described in an earlier number of *El Siglo*. The present contribution deals with goiter as it occurs in well-known localities in different parts of the world, and the author analyzes the various theories as to its nature. These are summed up as follows: Goiter and endemic cretinism appear to be the consequences of an infection. The cretin as a rule inherits his malady, but whether or not an infectious principle is handed down from mother to fetus can neither be affirmed nor denied. Sporadic goiter may be due to a variety of toxoinfectious causes. In Brazil the trypanum *Cruzi*, which causes Chagas's disease, can set up an infectious, hypertrophic thyroiditis as a result of the bite of an insect host, the *Conorrhinus megistus*. The geological argument in favor of a germ in certain soils cannot be narrowed down to particular formations, although the mountains, rather than the lowlands, furnish the cases. Good hygiene in all its forms always secures a rapid diminution in incidence. There is a certain connection of some sort between the drinking water and the disease. Crowding together, living with animals, and poverty in general are causal factors of importance, as shown by the fact that prosperity, removal from infected foci, etc., causes a notable falling off in cases. Not a few cases of goiter date from some infectious disease of childhood. Here the damage is permanent and the goiter remains as a stigma. It is subject throughout to exacerbations and remissions. Finally there is much evidence to suggest that the infectious principle is absorbed from the intestinal tract.

Case of Polyglobuly with Diminished Globular Resistance.—Jiménez Asua refers to splenectomized patients whose blood was studied before and after intervention. In one case cited the red cells numbered 6,500,000. The curve of globular resistance by May's method showed marked diminution. In this particular case operation was refused. The question of diagnosis in these cases is often very difficult as far as the precise splenic lesion is concerned. Polyglobuly, however, always arouses suspicion of tuberculosis of the spleen, although in the author's case this affection could probably be excluded. The great diminution in globular resistance which amounted in part to total hemolysis suggests hemolytic icterus, but this could be eliminated on several scores. Echinococcus of the spleen was suggested both by exclusion and by a positive Weinberg reaction and the diagnosis narrowed down to echinococcus and tuberculosis. In any case polyglobuly is believed to indicate destruction of the splenic parenchyma, from

whatever cause, by reason of its tendency to appear after splenectomy. It is then accompanied by nucleated erythrocytes and other evidences of hyperactivity of the medulla. But in splenectomized animals the resistance of the red cells may be increased, indicating regeneration, although in some researches fragility was a consequence. The problem is therefore very complicated and the author is forced to return to a consideration of his own case. The maximum resistance of the red cells was normal and the count showed no evidence of regeneration. The polyglobuly was therefore not compensatory. The minimum resistance touched total hemolysis, but only a small number of red cells were affected. In a large number major and minor resistance was normal. The author is forced to conclude that destruction of red cells was limited to old erythrocytes which were doomed to perish and which showed but slight resistance in May's test. The anemia in the author's case was of the chlorosis type, the hemoglobin showing from 65 to 70 per cent. This drop could perhaps be brought in relationship with the suppressed function of the spleen in connection with iron metabolism.

Physiologic Mechanism of Muscular Tonus.—Piéron writes an introduction to the subject of contractures. Muscle tonus and clonus are, he states, quite different phenomena. Tonic contraction is a slow, persistent action, in which the temperature is actually lowered, there is no waste of energy, no subsequent fatigue. During the contraction creatine is formed. The active portion of the muscle is the sarcoplasm and the innervation is derived from the sympathetic system. In clonic contraction conditions are reversed. The temperature is raised, energy is squandered, there is fatigue poisoning. Metabolism does not concern protein, but carbohydrate substances. The functioning element is the muscle fibrilla and the innervation cerebrospinal. Hence, muscle function shows a pronounced dualism—static and dynamic. Rapid activity is obtained only through great loss of energy, while the tonus of a sphincter muscle is maintained without energy loss. Naturally the smooth muscle produces a majority of the static effects in the body, as we descend in the animal scale. In the vertebrate the striated muscle exerts both functions. In other words, it is a double muscle for the production of both static and dynamic effects and is in part innervated by the sympathetic. There are tonic impulses which proceed from the cord, and approximately we know the centers and paths for such impulses. The former are in the cerebellum, red nucleus, Deiter's nucleus, etc., and possibly there are spinal centers. Concerning the sympathetic fibers, we have little exact knowledge. The part played by the ganglionic chains along the spine is certainly small dealing only with a residual tone. Variable tonus is maintained only through reflex activity, but there are cerebellar and cortical components. Hyper-tonus, contracture, may originate through irritation of the sympathetic, and is then accompanied by vasoconstriction. In commotional syndromes we see both hyper- and hypotonia.

Orthostatic Tachycardia.—Leven writes of a type seen in dilated stomach which is curable by gastropexy. The symptom vanishes when the subject lies down. In dilated stomach many symptoms ascribed to auto-intoxication are more plausibly explained by reflex activities. The author enumerates orthostatic hypertension, pallor, lassitude, albuminuria, dilated pupil, etc., which he explains by traction upon the celiac plexus. In relating a case the author speaks of the pulse of 120 when erect, as compared with 60 when recumbent. When the prolapsed stomach was elevated with patient standing the pulse at once fell to 60. In this case the organ reached the level of the pubes. After medical treatment had proved a failure gastropexy was performed. Improvement slowly followed until after two months the pulse frequency on standing was 72 and on lying down 56.

Recent Literature of Asthma.—The old teaching of Laennec that asthma represented a bronchospasm still holds good in part to-day, and can be shown

on the screen where the lung and diaphragm remain quite passive. The sputum count is quite characteristic. Asthmatic paroxysms suggest an anaphylactic phenomenon, but a capital distinction must be made between true and symptomatic asthma. It has been shown abundantly that asthmatic paroxysms may mean masked tuberculosis, and in children a cuti-reaction should always be taken, while injections of tuberculin may provoke a paroxysm. Later work showed that such phenomena need not be due to specificity, but merely to foreign protein. Such reactions are peculiar to younger subjects, while clinically asthma begins in middle life. Horse asthma, so-called, is common in mankind, and is of the same nature. Since the vagus enters into asthmatic crises it is readily acted upon by certain drugs like adrenalin, hypophysis extract, and atropine.

Le Progrès Médical.

February 23, 1918.

Genital Complications of Typhoid Fever.—Cade, Vaucher, and Huchon include paratyphoid infection in their study. These complications are very rare, but since the beginning of the war quite a number of cases have been seen in soldiers. Giroux reported two of orchiepididymitis which supervened during the course of a typhoid or paratyphoid, and was soon followed by Raymond and Parisot with a case of orchitis and suppurative vaginalitis due to paratyphus B. Olmer and Voisin then reported a series of three cases of orchiepididymitis, two of which occurred in typhoid patients, while the other was a complication of a *B. coli* infection. Raymond reported a suppurative case of orchiepididymitis in a clinical typhoid. To these seven cases the present authors add five, collected from various sources; so that our knowledge of this rare accident can now be recast. The cases are given individually, with a full summary as follows: of the five cases two occurred in typhoid and three in paratyphoid fevers (in two of the latter the *B. form* was present). The condition was invariably an orchiepididymitis, and unilateral. In four of the five cases the affection appeared during convalescence. In two (both paratyphoid B.) suppuration occurred. Despite the fact that the bacteria are eliminated in the urine, these localizations doubtless represent a blood metastasis.

Urology and Psychotherapy.—Uteau and Sauvage describe two cases as follows: Female, 22, consulted one of the authors for burning in the urethra and bladder at the end of micturition, and for frequent micturition. The pains seemed worse when she held her water. There appeared to be crises which lasted four or five days, during which she urinated every ten minutes in the day time and rose from twenty to thirty times every night. The urine was always clear, free from sand and blood. Menstruation normal. The author was able to palpate the left kidney, which seemed to be normal. The bladder capacity was 275 c.c. Cystoscopic examination was negative, as were most of the other tests. The x-ray gave some doubtful shadows. Methylene blue eliminated slowly. It was decided that the right kidney was prolapsed, which justified an incision. The kidney was fixed in the usual manner. No other affection coexisted. All went well for fifteen months, when there was a complete return of symptoms. No treatment availed, and the case was adjudged psychogenic. After nine weeks of psychotherapy—rest, isolation, re-education—patient seemed well again. Later she developed a series of ailments, as bronchitis, pertussoid cough, hemoptysis, etc. There was a cavity at the left base of the lung, and the legs became swollen. The bladder symptoms also returned. It was now judged that the nephropexy had cured by suggestion only. The report of the case breaks off abruptly. The second case, also of bladder irritability, occurred in a woman of 30. She was married and had one healthy child. The only other pregnancy ended in miscarriage. She could get no relief from her bladder symptoms. With the first case in mind, the patient was hypnotized, and proved to be very suggestible. She was then psychoanalyzed, her sexual life being laid bare from childhood. Certain obsessions were put to flight, and patient has remained well to date, some five months.

Book Reviews.

PRINCIPLES OF DIAGNOSIS AND TREATMENT IN HEART AFFECTIONS. By Sir JAMES MACKENZIE, M.D., F.R.S., F.R.C.P., A.B. and Ed., F.R.C.P.I. (Hon.), Physician to the London Hospital (in Charge of the Cardiac Department), Consulting Physician to the Victoria Hospital, Burnley. Third Impression. Price, \$2.50. New York: Oxford University Press, American Branch, 1917.

THE contents of this little book by Sir James Mackenzie were intended to be delivered in the form of lectures, but as the outbreak of the war prevented their delivery, the matter was divided into chapters, while the colloquial form of expression was retained. The work was written with the view of showing the general practitioner how to recognize certain conditions, which have hitherto been revealed by mechanical aids, as the polygraph and the electrocardiograph, by employing ordinary methods of examination.

Heart failure is very carefully considered and set forth in so practical and easily comprehensible a manner that all the essential facts connected with it can be appreciated and readily applied in practice.

The book is throughout of an eminently practical character, is clearly and concisely written, and will prove undoubtedly of the greatest value to the practitioner and student. Indeed it has already so proved, for this is the third impression, the first having appeared not long after the beginning of the war. It is superfluous to say that to James Mackenzie is largely due the greater knowledge and conception of heart affections which have prevailed during recent years. The book is worthy of the author.

THE FUTURE OF THE DISABLED SOLDIER. By C. W. HUTT, M.A., M.D., Cantab., D.P.H. Oxford, Deputy Medical Officer of Health County Borough of Brighton; recently member of the Brighton War Pensions Committee; Temporary Lieutenant R. A. M. C. Illustrated. Price, \$2. New York: William Wood & Company, 1917.

THE re-education and rehabilitation as far as is possible of the disabled soldier is easily one of the most serious problems of the war. The problem, however, has been and is being grappled with more or less success in the European countries and in Canada, and steps have been taken in the same direction in this country. Dr. Hutt deals with the whole question in a very thorough manner and describes the methods employed in most of the countries at war. The book is of great value at the present time and may be read with profit and interest by medical man and layman.

BLOOD PICTURES: AN INTRODUCTION TO CLINICAL HAEMATOLOGY. By CECIL PRICE-JONES, M.B. (Lond.), Capt. R. A. M. C. (T. C.), Bacteriologist, British Expeditionary Force; formerly Assistant Pathologist Middlesex Hospital Cancer Research Laboratories; Assistant Bacteriologist Guy's Hospital, London, S.E.; Pathologist East London Hospital for Children. With 5 Colored Plates and 4 Illustrations in the Text. Price, \$2.00. New York: William Wood & Company, 1918.

THIS book is a brief but concise treatise on blood pictures as they are encountered in everyday clinical work. It is intended primarily to assist physicians in the interpretation of reports on blood counts. The book is divided into two parts with three appendices. The first part has to do with routine methods of blood examination, description of blood cells, and the normal blood picture. In connection with the technique of blood counting, the author recommends the Bürker hemocytometer as being superior to the old Thomas-Zeiss form, the particular advantage of the former instrument being the fact that two different bloods may be counted at the same time. This is a question largely of individual preference. The Haldane hemoglobinometer, an instrument quite popular in England, is used very little in this country. It has the disadvantage of requiring the use of coal gas to convert the bright hemoglobin into carboxyhemoglobin. The writer's statement in regard to the estimation of blood platelets being of little value is not in entire agreement with the newer researches on the coagulation of the blood,

hemophilia, purpura hemorrhagica and blood dyscrasias generally, in which conditions enumeration of these bodies is of decided value. The colored plates depicting normal and abnormal blood cells enhance the value of the context considerably. The second part takes up blood pictures in their relation to the diagnosis of disease. The influence of bacterial and protozoal infections on the blood is given in detail and is illustrated by selected type cases. The anemias and leucemias are next discussed. The reader obtains a clear conception of the significance and diagnostic criteria of these conditions without being burdened unnecessarily with academic dissertations. Blood changes in malignant disease conclude this part. The appendices are devoted to a short statement on the preparation of stains with their methods of application, the measurement of red corpuscles, and finally a chart on the origin of blood cells is inserted. Altogether the book forms a very useful contribution to the subject of clinical hematology, particularly on account of its lucidity and practical character.

A BRIEF INTRODUCTION TO THE GENERAL PRINCIPLES OF THERAPEUTICS. By FRANCIS H. MCCRUDDEN, S.B., M.D., Director of Laboratories, Robert B. Brigham Hospital, Boston, Assistant Professor of Applied Therapeutics, Tufts Medical School, Boston. Price, \$1.50. Boston: Gregory, 1917.

THIS is an elementary textbook dealing with the principles of therapeutics. But it is an elementary textbook founded upon a scientific basis and is adapted for the use of those who are learning the principles of therapeutics. The book treats of the subject as a branch of applied physiology, an excellent method of considering the matter which, up to the present, has been overlooked.

THE TREATMENT OF INFANTILE PARALYSIS. By ROBERT W. LOVETT, M.D., John B. and Buckminster Brown Professor of Orthopedic Surgery, Harvard Medical School. Second Edition, Revised and Enlarged, with 123 Illustrations. Price, \$1.75. Philadelphia: P. Blakiston's Son & Co., 1917.

SINCE the issue of the first edition of this excellent work, Dr. Lovett, owing to the widespread epidemic of poliomyelitis in this country, has had exceptional opportunities for close and protracted study of the disease. In New York State he was enabled by the courtesy of the State Department of Health to supervise an enterprise for public treatment in that State which embraced some 2500 cases.

Dr. Lovett believes and he emphasizes this point in his book that by taking the therapeutics of the convalescent and chronic stages of infantile paralysis more seriously and by ceasing to regard the affection as a more or less hopeless condition, a class of results will be obtained such as have not heretofore been reached.

MANUAL OF MEDICINE. By THOMAS KIRKPATRICK MONRO, M.A., M.D., Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow; Regius Professor of Practice of Medicine in the University of Glasgow, and Physician to the Western Infirmary. Fourth Edition. Price, \$6.00. St. Louis: C. V. Mosby Company, 1917.

THIS, the fourth edition of Monro's well-known manual of medicine, has been thoroughly revised and altered. Among the changes made is the placing of acute poliomyelitis among the infections, while beri-beri has been removed from the infections, and together with scurvy removed from diseases of the blood included among constitutional diseases. Six polygraph tracings have been introduced which, in the words of the preface, when examined along with the descriptive legends, will enable the student to interpret the more common varieties of polygraph curves, and to understand how fruitful this mode of analysis of the cardiac action has been in the hands of Mackenzie and his followers. The diseases of the ductless glands have been considered in the light of the most recent investigations, and acromegaly has been placed among them. New short articles have been introduced on Vincent's Angina, Chronic Interstitial Enteritis, on Epidemic, on Trench Nephritis, and on Trench Foot. The manual is concise, but comprehensive, and should provide an excellent work of reference.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held March 7, 1918.

THE FIRST VICE-PRESIDENT, DR. GEORGE D. STEWART,
IN THE CHAIR.

THIS meeting was held under the auspices of the Public Health Committee of the Academy, the subject being "The Prevention of Disease in War Industries."

Extent and Importance of the Problem.—Dr. DAVID LINN EDSALL of Harvard University, in presenting this phase of the problem, stated that the first thing the clinician needed to do was to divorce his mind from the idea that industrial diseases meant only such diseases as poisoning by lead or by other substances used in the industries. A much greater number of factors than poisons were important in relation to health in industrial life. There was no way of knowing in this country in general how many cases of disease were due to conditions encountered in industrial life, because of the lack of any general reporting, recording, and investigating, of this class of diseases, nor could we tell to what extent such disease existed at any particular time in this country. In an investigation of the manufacture of explosives, in 1916, Dr. Alice Hamilton found that there were about 30,000 persons at one time exposed to poisoning in this work and over 2500 cases were found, confirmed by medical diagnosis, in which more or less serious poisoning had occurred in this kind of work. The number of cases of disease due to the new war industries was not really known, however. Dr. Hamilton pointed out that the number of cases recorded by no means represented all the cases of disease due to these causes. There was no question that the number of cases was much greater than Dr. Hamilton could find at that time and the number had unquestionably increased since then in consequence of the increase of war industries. But beside these definite war industries many others exposed to poisoning, an important one of such poisons being lead, which was responsible for a great many cases of poisoning in other industries as well as in the war industries. More persons were exposed to lead poisoning than to all the distinctive war poisons, and that there were a great many more cases of lead poisoning than we were accustomed to thinking was shown by studies made at the Industrial Clinic of the Massachusetts General Hospital where they had made a special study of this subject. They had been interested in studying this matter before the war. In order to investigate this subject, in every case admitted to the hospital a record was taken of the patient's occupation, whether he was admitted to the hospital wards or to the out-patient department. They listed both the industry in which the patient was engaged and the patient's occupation in that industry. They employed a social worker who was given a list of industries and of the diseases likely to be caused by each industry, and she soon was able to recognize the cases in which there was a likelihood of industrial disorder, and every case in which she thought there was a possibility of the existence of an industrial disease she sent to the industrial clinic for examination. In that way an approach was made to getting all the cases in which industry had anything to do with the disturbance of health. In the five years preceding the inauguration of this system, 146 cases of lead poisoning were found in the wards and out-patient department of the hospital. During the first year in which the industrial clinic was conducted, 148 cases of lead poisoning were recorded, more than during the preceding five year period. These cases of lead poisoning were determined by known exposure to risk of lead poisoning, by definite clinical evidence, and by looking for and finding lead in the urine and stools. That showed how much more frequent lead poisoning might be than we had supposed it to be. Hence we must believe that poisoning by lead and other substances used in industry was very important. But we must also recognize that other effects of industry were more important in their influence upon health. During this year mentioned above there were over 5100 patients sent to the industrial clinic in which the health disturbance might have had some relation to occupation.

In the great majority of these 5100 cases the hazard was recognized because of a little trained knowledge but would otherwise have been overlooked. There were nearly 500 cases in which it was shown that the industry in which the patient was engaged was the controlling factor in producing the disturbance of health, besides many more in which it was a partial factor.

In ordinary work, and particularly in hospitals, Dr. Edsall said, we were overlooking one of the most important causes of ill health, unless we adopted accurate methods of studying this question. There should be an accurate method of studying the relation of industry to health in every hospital where large groups of people were dealt with. Medical schools had neglected the opportunity of training students into a comprehension of this subject which was one of the most important etiological factors in medicine and one which hitherto had been given but casual mention. It had now become so much more important than formerly that he believed the medical schools, hospitals, and all medical organizations, should have some more definite method of instructing medical students and practitioners in the effects of industry on health and in carrying on investigations of this subject.

Aside from the specific hazards of injury there were many other factors involved such as general hygienic surroundings, toilet and washing facilities, proper light, ventilation, and various other factors, that must be investigated. Then there were a number of problems which were partly medical, but more largely social and economic. And in order to be able to secure proper care in respect to these various factors the public must be educated to their importance. The question of transportation did not impress one at first thought as a medical matter, but it was an important factor in connection with health conditions. In England, the rapid growth of munition plants made it necessary in some localities for the workers to travel even two hours daily each way in going to and coming from their work; this produced an additional fatigue that must be taken into account in connection with health problems. This same state of affairs as regards travel to and from work was rapidly coming to the foreground in this country. There was a variety of other questions which were emphasized by the Committee working on Industrial Fatigue. The workers in England came to work ill fed oftener than in this country, it being customary there to put in several hours work in the morning before having a meal, but they are frequently ill fed here. It must be recognized that fatigue was probably the most important factor in the production of ill health and all these things came within the scope of the problems of industrial health, and particularly hours of labor, rest periods, night and day work, and the like.

In recent years the question had come up of fitting the individual to his job, and no one, until he had undertaken to study the problem, realized what an intricate and important problem it was. Dr. Edsall referred in this connection to the work of such men as Dr. Clark of Worcester, who in very heavy work declined for physical reasons only about three per cent. of the applicants for work. He took individuals with organic heart disease and other conditions that off-hand seemed to unfit them for work and fitted them to do some work that they could do. By proper adaptation a large percentage of somewhat incapacitated people were actually improved by the work to which they were assigned. Dr. Edsall said that from what he had indicated it was evident that the problems involved were so numerous and so extensive that we could not attempt to bring about ideal conditions at the present time, but the question was "What is most important now?" Some persons argue that at the present time it would be very unwise to make changes, for such a move might have the effect of slowing up industry. We might perhaps argue that it was better to sacrifice some lives in industry as well as on the battlefield if that were necessary to win the war. But the prevalence of ill health among employees had the effect of greatly slowing up industry. Leading manufacturers had introduced methods of safeguarding their employees because they had found that losing skillful men interfered with production, so they protected their employees to save disorganization of the work.

Things that should especially be done were to devise

a method of establishing minimum regulations for industrial plants and then by a system of inspection to see that these regulations were carried out. These regulations should be Federal regulations and there should also be Federal supervision. In the states in which these things were well carried out under state law the Federal function might be advisory rather than supervisory, while in states in which they were not so well managed there should be Federal supervision. It might be well to put this work in the hands of the United States Public Health Service, though the place in which the authority was vested was not so important as that such a plan should be carried out. Provision should be made for the medical observation of people exposed to industrial hazards. We should also have a definite recognized body for carrying out investigations and for keeping a watch for and protecting workers from new dangers that might arise in connection with the activities incident to the war. Tetrachlorethane poisoning became frequent in England in the early years of the war. That form of poisoning was properly investigated and eliminated by eliminating the use of tetrachlorethane. Someone should have the responsibility of keeping a watch for other instances in which hitherto unrecognized hazards might be responsible for injury to the health of the workers. There were certain features in connection with the relation of industry to health in which not only certain special groups of physicians, but the entire profession should take an interest, namely: (1) The reporting of industrial diseases, keeping before the public the relationship of industry to health, giving these subjects more attention in the medical journals, and keeping the profession informed regarding cases seen; (2) Some medical men should be made more expert in these subjects. More medical men should be trained to recognize and deal skillfully with industrial diseases; (3) There should be men trained in the supervision and examination of employees.

In closing Dr. Edsall stated that if some plan of controlling industrial health were adopted many opportunities for individual physicians to be of service would develop. Industrial medicine was a technical specialty and required just as much special training as any other branch of medicine, in order that an individual might be adequately fitted for service. Should such suggestions be carried out there would be need for a number of men who could do the work adequately, and it would then perhaps be desirable as a war measure to establish centers for intensive study of industrial health just as there had been established schools for the study of surgery of the head, for the study of the treatment of pneumonia, for the study of orthopedic surgery, and of other branches in which many men with special training were required to meet the present demand.

New Poisons in War Industries.—Dr. W. GILMAN THOMPSON spoke briefly on this subject and gave a lantern slide demonstration illustrating conditions in different industries that were responsible for disturbances of health. He stated that the cases of poisoning met with in industry were most important and exceedingly interesting both from the economic and medical point of view. They were interesting from the economic standpoint because the men suffering from these conditions were incapacitated in many instances, in some efficiency was markedly impaired, and in others the poisoning resulted fatally. From the medical side these cases were important because they showed a new and interesting combination of symptoms. For the most part these symptoms were imperfectly known; they had not been definitely delineated until they were brought to notice by the conditions incident to the war. In the investigation of the diseases due to poisoning by substances used in the manufacture of munitions the first work was done in England and in a general way these diseases were classified as follows: (1) Those caused by the inhalation of gases, the fumes of which might gain access to rooms where the men were working. In most cases of poisoning caused by these volatile gases the onset of the symptoms was acute. (2) The second group of cases were those caused by handling certain nitro and amido compounds and especially by phenol, benzol, and toluol. These substances were all very poisonous. The nitro-compounds became progressively more and more poisonous the longer the

workman was exposed to them and constituted a menace not alone to the workman employed continuously where these compounds were used, who was taught to protect himself, but to the casual worker who comes in to perform a special piece of work, as, for instance, to clean out a retort or repair steam pipes. Dr. Alice Hamilton reported two cases which she investigated where the men went in to clean a tank. The poison acted promptly, one man became delirious and in attempting to get out plugged the opening of the tank, so that the second man got no air, and both were killed in a very short time. There had been many instances reported in which a casual worker had been overcome by gas because he was unwarned and unprotected from such a serious hazard. Sometimes in the second group of cases poisoning occurred from handling phenol, benzol, or toluol. These poisons produced definite symptoms affecting the central nervous system, such as dizziness, headache, transient excitement, depression and nausea, followed by coma. In mild cases the symptoms were like those of alcoholic intoxication. In fatal cases in which death had not ensued too rapidly the viscera had been found congested; there were hemorrhages and degenerative changes in the liver. Trinitrotoluol was one of the nitrite group which produced changes in the blood, destructive changes in the epithelium, and fat embolism. It gave rise to hemorrhages and to a marked lymphocytosis as pointed out by W. G. Hudson. The changes induced by this poison were most characteristic and this was fortunate as it made it possible to detect the condition early. It was not an acute condition, but one which it took a month or two to develop to an extent to which the patient became incapacitated. There were definite changes in the hemoglobin and in the bile and the patient presented a peculiar livid yellowish color as the disease progressed. Sometimes the additional symptoms of abdominal cramps, diarrhea, or constipation were present. The patient sometimes became unsteady, staggered, became delirious, and coma set in. In some instances there was edema of the legs. It might be seen from this summary of the symptoms that the condition was a serious one, acting mainly through the central nervous system and changes in the blood. If death occurred from trinitrotoluol the changes in the liver were similar to those found in acute yellow atrophy. The method of manufacture involved the problem of working with strong acids and washing the product to render it neutral. When this substance in a pasty condition was placed in the large shells it might spill on the outside of the shells where the men who handled them would come into contact with it. Several of the pictures showed men working without respirators, gloves, or special protection for other parts of the body. It was possible to make regulations requiring workers to wear these protectors, but it was a very difficult matter to make the men pay due attention to the use of such protectors. Dr. Thompson referred to the danger of pneumoconiosis in industries in which the workers were exposed to the dust of brass or other metals. He knew of some instances, however, in which men had been exposed to this hazard for a considerable period of time and seemed to have become immune to it. The problem was to prevent the hazards of industry and nearly all of them were preventable. It was exceedingly gratifying to know that when the manufacturers had their duty pointed out to them in respect to the protection of their employees they were usually ready to cooperate. They looked to the physician, however, to tell them how to bring about the results that were desirable. The physician should point out the advantages of adequate toilet and washing facilities, lunch-rooms, etc., in connection with industrial plants. The special committee of the Council on National Defense which has this work in charge has formulated health standards for munition workers, and at a recent conference of munitions industrial leaders the manufacturers were willing to adopt them voluntarily. If the necessary protection for the workers could be obtained through voluntary cooperation it is better than to legislate, for under present circumstances industrial conditions are changing all the time and legislation that was desirable at one time might soon fail to meet requirements.

Methods of Prevention and Control.—Dr. JOSEPH W. SCHERESCHEWSKY, Assistant Surgeon General, United

States Public Health Service, read this paper. (See p. 585.)

Aid from the Medical Profession.—Dr. ALFRED STENGEL of the University of Pennsylvania, Philadelphia, read this paper. (See p. 587.)

Resolutions.—Dr. CHARLES L. DANA, in behalf of the Public Health Committee of the Academy of Medicine presented the following resolutions: "1. That the matter of the need of instruction in the recognition, treatment and prevention of occupational diseases should be brought to the attention of the authorities of the medical schools of New York City, with a request that a special course be given through at least one term, with particular reference to the numerous poisonous substances used in industry and their deleterious effects. 2. That special clinics be organized under the auspices of the medical schools in order that occupational diseases may be studied and treated under competent guidance and supervision. 3. That consideration be given to the desirability of the establishment of special clinics, under the auspices of teaching institutions and health agencies, in the neighboring towns of New York City, where large manufacturing and munition plants are located, with a view to facilitating the utilization by the men and women employed in these factories of the thus established medical opportunities. 4. That the representatives of the large hospitals and dispensaries be impressed with the importance of accurately recording the details of occupation of all patients entering the institutions, and collecting data regarding them, and the need of providing adequate facilities for their treatment. 5. That the importance of early recognition of occupational poisons be brought to the attention of medical practitioners of this city, and that they be urged to report such cases promptly to the City Department of Health in order that better follow-up supervision may be provided. 6. That the medical press be requested to give more space to the discussion of occupational diseases than they have hitherto. 7. That proper educational facilities be established by the State Industrial Commission and the New York City Department of Health in order that the large number of men and women working in hazardous trades should understand the nature of the hazards and know how to avoid them, and to seek early medical advice when the first symptoms of poisoning appear. 8. That the excellent work done by the Bureau of Occupational Diseases of the New York City Department of Health be encouraged and means provided for its extension. 9. That the manufacturers be impressed with the importance of safeguarding the health of employees through adequate medical supervision, efficient factory sanitation, and the prevention of occupational diseases. 10. That the Federal Government, in the interest of the conservation of the health and efficiency of the workers, be requested to co-operate in the effective supervision over the conditions prevailing in factories producing munitions of war and other allied products, through the corps of experts associated with the United States Public Health Service." These resolutions were referred to the Council.

SECTION ON SURGERY.

Stated Meeting Held March 1, 1918.

DR. SETH M. MILLIKEN IN THE CHAIR.

Intussusception with Resection; Recovery.—Dr. EDWARD W. PETERSON presented two cases. He stated that his reason for bringing them before the Section was because of the infrequency of recovery after resection for irreducible or gangrenous intussusception in infants and young children. In a search of the literature he had found only ten or twelve cases in which recovery had taken place in infants when bowel resection was necessary.

CASE I.—This patient was a well nourished, breast-fed infant, eight months old, of Austrian-Hebrew parentage, admitted to the Post-Graduate Hospital on May 16, 1917, with a history of having been acutely ill since the day previous with severe attacks of abdominal pain intermittent in character, persistent vomiting, and mucohemorrhagic stools (two). When seen by the speaker the patient had a temperature of 101° F.,

pulse 160, and respiration 36. Abdominal palpation revealed an indefinite abdominal tumor on the right side. On this group of symptoms and signs a diagnosis of intussusception was made. The previous history of the patient showed that for some months the child had suffered from gastrointestinal upsets, with spasms of abdominal pain, and loose, green, undigested stools, about three in twenty-four hours. When about four months old he had such an attack, with blood in the stools, which was highly suggestive of intussusception with spontaneous disinvagination. For a week previous to his admission to the hospital he had suffered from the symptoms described above. At operation a right rectus incision was made and the intussusception was found at once. Owing to the edema, reduction was difficult. It was found that the ileo-cecal valve formed the apex of the invagination. The most interesting point was that the last two inches of ileum, not involved in the invagination, contained a soft tumor mass. Believing this to be the cause of the intussusception, and wishing to determine the nature of the growth, the ileum was opened. The new growth, for such it was regarded at the time, had the appearance of a papillary angioma, being purplish in color, soft, and cauliflower-like in appearance. A resection seemed to be indicated. The lower ileum and the cecum were removed, followed by an end to end anastomosis between the ileum and ascending colon with a small Murphy button. The patient had a stormy convalescence, a rather troublesome enteritis developing, but at no time was he critically ill. The Murphy button was found in the rectum on the sixth day, and was removed under light anesthesia. The patient was discharged from the hospital on the fourteenth day. Dr. Peterson presented the specimen removed, together with the pathological report. The specimen consisted in a section of gut taken from the ileocecal valve and measuring 6 cm. in length. Just anterior to the ileocecal valve was a definitely outlined mass raised 5 cm. from the surrounding mucosa, having a corrugated area and covering an area of 6 sq. cm. It was soft in consistency. The microscopic examination showed the entire mucosa and submucosa of the gut markedly congested, edematous, and hemorrhagic along the surface. One portion of it projected outward in folds, was eroded at the surface, and consisted of large numbers of greatly hyperplastic lymph follicles with a few mucous glands intermixed. The condition appeared as if it had resulted from a previous intussusception with the consequent congestion, hemorrhage, and inflammation. It was highly probable that this portion of the mucosa had been within the ring of an intussusception and that the constriction upon it was the principal cause of the peculiar appearance of the condition in the gross.

CASE II.—Dr. Peterson stated that this patient, a boy four and one-half years of age, was seen, in consultation with Dr. Alperin and Dr. Dennett, on December 26, 1917. The previous history was unimportant. During the past three months the patient had suffered with two mild attacks of pain in the right lower abdomen. He had had measles three weeks before and was just recovering from this illness. On December 22, 1917, he was seized with severe abdominal pain, paroxysmal in character, and vomiting. During the five days of illness, before admission to the hospital, the bowels never moved satisfactorily, although some flatus was expelled when stimulating enemata was given. At no time was there any blood passed. An enema given at the hospital was returned without gas, blood, or feces. (On December 25 a prominent consultant had ruled out intestinal obstruction as a cause of the illness and had made a diagnosis of "tuberculous meningitis.") When examined by Dr. Peterson the patient's general condition did not appear critical. The abdomen was considerably distended, visible peristalsis was present, and tumefaction could be made out on the right side. A diagnosis of intestinal obstruction was made, but intussusception was not thought to be the variety of obstruction present. When the abdomen was opened, through a right rectus incision, the much distended small intestine crowded out of the wound. The cause of the bowel obstruction was found to be a double intussusception (ileo-ileocolic). A Meckels diverticulum, about 25 inches above the ileo-cecal valve, was the causative factor. It was found that the ileum was gangrenous, and rupture at several points occurred when reduction of

the invaginated small bowel was attempted. Beginning about 10 inches above the ileo-cecal valve, and going well above the diverticulum, a resection of the damaged gut was performed, followed by an end-to-end suture anastomosis. Following operation the boy was profoundly toxic for several days, with temperature 104.8° F., pulse 172, great abdominal distention, and persistent fecal vomiting. Systematic lavage of the stomach, the use of pituitrin and stimulating enemata, and the administration of fluids by proctoclysis, hypodermoclysis, and intravenous infusion finally brought the patient through the critical period, and three weeks later he was able to leave the hospital cured. In looking over the literature of intussusception in early life, Dr. Peterson stated, in addition to his own successful case of resection of a gangrenous intussusception, reported in detail in the *MEDICAL RECORD* in 1905, that he could find but one other recorded success, the operation in this instance having been performed by Dr. W. S. Schley of New York. Dr. Peterson would be glad to learn of other successful cases, if such had escaped his notice.

Dr. CHARLES E. FARR congratulated Dr. Peterson on the fortunate outcome of his cases of intussusception with resection. He said that he had never seen any cases similar to these in which recovery took place; all died.

Dr. ALEXIS V. MOSCHCOWITZ said he voiced the sentiments of Dr. Farr; in all cases similar to those reported by Dr. Peterson in which he had attempted resection the outcome had been fatal. He thought there were two reasons why these cases usually terminated fatally. In the first place, the patients usually came in very bad condition, and, in the second place, they occurred in very young children. One of Dr. Peterson's cases was four and one-half years old and in good condition to withstand the operation, and that is one reason why his patient recovered. A further point that interested him was that the boy had a temperature of 104° F. after the operation. It had been his experience that even when the operation was successful and the case had come to operation fairly early, so that the intussusception could be reduced and the abdomen closed, there would be a very marked temperature reaction to 104° or 105° F. This was probably due to some form of toxin that was liberated from the invaginated gut.

Dr. CHARLES R. L. PUTNAM cited two instances in which he had operated for intussusception in which gangrene was present and the patients recovered. One of these intussusceptions occurred in the ileocecal region and the other in the ileocolic region. In one instance the intestine was so thickened, so hemorrhagic, and so friable that the entire lumen was involved and the gut had to be resected. In these cases the toxic symptoms usually occurred within twenty-four hours after operation, but after the lumen of the intestine was opened up again they passed over.

Dr. PETERSON, in closing, emphasized the point that these two cases *did recover after a resection*, and that such an outcome was exceptional. If these cases were seen early he thought one might expect success, but in late cases, after gangrene had set in, it was most remarkable to get a recovery, as proved by the fact that there were only three cases on record. He had had a case in which he did a simple reduction of an intussusception and the patient's temperature went to 107.8° F. afterwards. There seemed in these cases to be some damage to the mucosa which resulted in the development of a biochemical toxin, causing the profound toxemia, according to Dr. Draper. Dr. Kerley said that the patients were so dehydrated and the lower gut so starved out, that it readily absorbed the toxins set free, and that this accounted for the violent rise in temperature that one saw in these cases after reduction of the invagination.

Tuberculous Glands of the Neck Treated by X-Rays.

—Dr. JAMES A. CORSCADEN presented this patient, a young woman. He stated that he was not presenting her as a case of tuberculous glands "cured by the x-ray," as he was trying to eliminate that expression from the nomenclature, but rather to call for discussion as to the value of the x-ray treatment in these cases. The history of the patient showed that her trouble began in 1911 with painful swelling in the right side of the neck. This went on for several weeks and finally

was incised. The patient then went along until the speaker first saw her, in 1917, having a continuous series of open sinuses in her neck. These had been treated by simple local cleansing and some attempt at general hygiene directed to the cure of the tuberculosis. She had twenty to thirty sinuses from 1 to 2 cm. deep, and there was more or less tuberculosis of the skin in the area involved. All who saw the patient agreed that it would be very difficult to excise all the glands that were involved; it would have required too extensive an excision of the skin and cause almost certain sloughing. The patient was then started on local x-ray treatment, after her teeth had been extracted and her head cleansed. The x-ray dosage was given on the theory of the cure of tuberculosis by the excitation of a local inflammatory reaction. The x-ray treatment was given at two or three week intervals, the amount administered being one-fourth the erythematous dose. This was kept up until July, 1917, when she was doing so well that further treatment was stopped. The last sinus healed in August, 1917. In January, 1918, the patient was seen by Dr. Hanford when there seemed to be a slight recurrence of the trouble.

Dr. Corscaden emphasized the fact that he was bringing this patient before the Section merely in order to attempt to get a true estimate of the position of the x-ray treatment of these glands. The question that now presented itself in connection with this patient was merely the academic one of whether to excise the affected glands or to apply the x-ray treatment. The antagonism that existed between surgeons and users of x-ray in the treatment of tuberculous glands was most unfortunate, and he thought it would be interesting to get the ideas of the members of the section on all the methods of treating tuberculous glands of the neck in order to properly apply each. In this instance the glands involved were all superficial cervical glands and the foci of infection that could be found had been removed from the teeth and the hair.

Dr. ROBERT T. MORRIS expressed the opinion that many more cases of tuberculous cervical glands treated by the x-ray should be reported than were being heard from. He stated that he had sent a great many cases of tuberculous cervical glands to the roentgenologists and he knew of many cases that did nicely under this treatment. He did not at the present time recall any cases in which the involvement was as extensive as in the patient presented this evening. For a number of years he had not been operating on tuberculous cervical glands unless they were broken down. He had tried many methods of treating these glands and found that with the Dollinger method of injecting iodoform emulsion, but it was a troublesome method, a number of these patients recovered. The x-ray was curative in a good many cases. Another procedure that he had employed included Bier's hyperemia principle. A hyperemia was brought about by having the patient lie with the neck against an icebag and against a hot-water bag alternately for a while every day, thus producing a hyperemia which would result in a condition inimical to tubercle bacilli. Dr. Morris emphasized the importance of eliminating any focus of infection that might be present in the tonsils or elsewhere. His experience had been such that he seldom operated on tuberculous glands of the neck now, although he once operated frequently.

He also emphasized the importance of carrying out the general treatment for tuberculosis in patients having tuberculous glands of the neck. The employment of tuberculin and of the best medical resources would often prove to be curative without any surgery at all.

Dr. EDWARD W. PETERSON said that where one had a large mass of tuberculous glands, and Hodgkin's disease and syphilis could be excluded, they should be taken out. Where such glands were broken down he thought it might be advisable to use the x-ray. He had found that many cases treated early by the x-ray did not respond to this treatment and when this happened and it became necessary to operate later on, the operation was likely to be much more difficult, because there was a fibrosis following the x-ray treatment that made dissection difficult. If there was a focus of infection in the tonsils or elsewhere, that of course should be eliminated. It was estimated that in frank tuberculosis of the cervical glands the tonsils were the seat of tuber-

culous infection in 50 per cent. of the cases, indeed one authority placed this estimate at 75 per cent. If one got these cases early and removed the tonsils either at the time the glands were removed, or else did the two-stage operation, the results were likely to be more permanent than when they were treated by the x-ray alone. Following operation Dr. Peterson advocated the use of the x-ray and tuberculin as prophylactic measures against recurrence.

Dr. CHARLES E. FARR asked how any one of those present would feel if he had tuberculous glands of the neck, whether he would be willing to delay while x-ray treatment was given if he knew the glands could easily be removed by operation.

Dr. CHARLES R. L. PUTNAM said he would not feel like submitting to an operation for tuberculous glands of the neck—that he felt very much as Dr. Morris did on the subject. He would have the foci of infection removed, would employ the general hygienic treatment for tuberculosis, and would use tuberculin. It was true that if there were broken down glands it might be well to excise them. He would try to protect the patient from further dissemination of the infection and then treat him for one or two years with tuberculin. He had employed this procedure over and over again with success even in patients in whom the glands were red and broken down and the patients had been able to go about their usual occupation during the time they were under treatment, and they got well.

Dr. ALEXIS V. MOSCHCOWITZ said the situation in regard to the treatment of tuberculous glands of the neck was somewhat confused. In the literature it was stated that the proper treatment, if not the only one, for this condition at the present time was the x-ray. He had given the subject a very careful tryout, and had mapped out the following routine at Mt. Sinai Hospital, where all cases of this nature were admitted to his service. The first thing he did with these patients was to examine the teeth, tonsils, and adenoids, and as a result of this examination they had found that in cases in which the glands were involved on one side only, the teeth or tonsils on that same side would harbor the focus of infection. In cases in which there was a bilateral involvement of the cervical glands, it was found that the adenoids were the focus of infection, as practically only in this way could a bilateral infection be accounted for. Also at the time of admission the physician in charge of the x-ray therapeutic department, Dr. Stern, was notified, and if he thought they were suitable cases for x-ray treatment, they were turned over to him for that treatment. Dr. Moschcowitz had agreed to operate on some cases which were pronounced as cured, but he still found a large amount of tuberculous material present. In addition Dr. Moschcowitz also found that the operation was decidedly more difficult on account of the fibrosis induced by the x-ray. In answer to Dr. Farr's question Dr. Moschcowitz would say that if he had tuberculous glands he would prefer to have them excised.

Dr. ELLIS BONIME referred to his experience in the treatment of tuberculosis by tuberculin, and expressed the opinion that this was the ideal treatment for tuberculous glands, especially in children. A course of tuberculin was the first treatment indicated. Some of the glands treated in this way healed by cicatrization and so shrunk and only partially disappeared, offering an ideal condition for removal. The cases suitable for surgery were those in which a tumor had been left after treatment with tuberculin. On the other hand the vast majority of tuberculous glands disappeared during the course of the tuberculin treatment. A large percentage of cases recurred after surgical operations of the most radical nature and after repeated operations either on the same area or over new areas, only to find the infection spread to the mediastinal glands. The tuberculin, on the other hand, exerted its influence on every nidus of infection.

Dr. ISAAC LEVIN stated that he had had some experience with tuberculous cervical glands in the course of thirty years of practice. Some years ago we did not know as much about the portal of entry of the tubercle bacilli as we did now and we saw many more of these cases of tuberculous glands than we did to-day. He had seen many cases both in his former home in Petrograd and in this country, the condition being very common

both among the Italians and the Jewish population on both sides of the Atlantic. Formerly tuberculous glands of the neck were considered purely a surgical condition, but it was well known that operation was followed by many recurrences. Surgery was not such a panacea that it was unnecessary to look for any other method of treatment for tuberculous glands. The x-ray cured tuberculous glands just as it cured cancer by diminishing the size of the foci, but it left a nidus of either cancer or tuberculosis surrounded by good stroma and new connective tissue, thus encapsulating the focus where it might be left alone or operated upon. Operation opened up the lymph channels allowing the infection to spread, while a small area of tuberculosis encapsulated in the lungs or elsewhere might remain for years without causing trouble, and the patient presented practically a clinical cure. In the speaker's opinion it was a perfectly correct policy to treat tuberculous glands of the neck by radiation which would diminish their size until they became merely shot-like nodes. Such nodes it was better to leave severely alone without operation. It was true that there were cases which were not cured by radiation and there might be a little central abscess following for which surgery was a perfectly correct treatment. Where there was a central focus one might begin with radiation first, and if that did not effect a cure one might then resort to operation.

Dr. CORSCADEN, in closing the discussion, emphasized that he had merely shown the case to obtain an expression of opinion. As yet we did not know the letters of the alphabet so far as x-ray treatment was concerned. We were dealing with an agent the fundamentals of whose action rested in the realm of physical chemistry, we knew little about its physics and less about its chemistry. For that reason he would hesitate to express a final judgment. He hoped that the discussion would stimulate them to study the subject more carefully so that they might reach some decision as to which of the many ways of treating tuberculous cervical glands was of the greatest value. The excision of tuberculous glands was not a cure; it was simply removing that part of the body in which the disease happened to lie. In the use of the x-ray in the treatment of tuberculous glands one was following along the lines found effective in the cure of tuberculosis by other methods by exciting inflammation about the focus or by passive congestion and fibrous tissue formation. A complete series of blood counts was not made in this case, but counts were made covering several days after some of the exposures and during that time there was no change in the blood count. The form of x-ray treatment to which Dr. Levin referred would be 100 to 150 times as severe as that administered to this girl; she had only one-fourth the erythematous dose at long intervals for six months. There was no scar tissue formed by a dose of that strength; the x-ray in the amount given simply stimulated the surrounding tissue to resistance. The Wassermann test was given and was negative in this case.

Surgery in Associated Stigmata of Decline.—Dr. ROBERT T. MORRIS delivered this address. (See p. 589.)

Dr. MOSCHCOWITZ agreed with Dr. Morris that there was a class of patients who presented these various stigmata and who were the bane of the surgeon. Surgery never cured them, but they sought relief and the surgeon lacked the courage to refuse to make an effort to help them even though he felt that it would be futile.

Stereoscopic Radiographs of the Pelvic Blood-Vessels.—Dr. HENRY DAWSON FURNISS presented stereoscopic radiographs illustrating a study undertaken to show: (1) the degree of anemia that could be produced by the ligation of certain vessels or groups of vessels, (2) the most effective methods of producing anemia for surgical operations; (3) the minimal amount of blood supply compatible with adequate tissue nutrition. The study was conducted by injecting into the arterial system a mixture of red lead and alcohol, after the ligation of certain vessels; after the removal of certain ligatures further injections were made and other radiographs taken. This was continued until all the ligatures were removed. The results of the study demonstrated: 1. That with ligation of the common iliacs and the ovarian arteries, the only vessel filled in the pelvis was the superior mesenteric. 2. Release

of the ligature on the external iliac made little or no difference in the filling of the pelvic vessels. 3. The internal iliacs could be filled through only one ovarian and the ovarian through only one internal iliac. 4. No experiment was made with the ovarian and iliac tied, but this would be done in subsequent studies to determine if any of the pelvic vessels could thus be filled.

Improvisation of Hospital Apparatus.—Captain JOHN C. A. GERSTER, M.R.C., sent illustrations and a brief description of improvised hospital apparatus, which were presented by Dr. Milliken. Among the articles was a dressing cart, a food car, a wheel stretcher, an apparatus for elevating the front or back castors of a bed, etc. They were all constructed of wood and could be made in camp at a nominal cost, thus saving space in the shipping and the cost of labor.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting Held February 27, 1918.

A Case of Congenital Syringomyelia (?)—Dr. MILTON K. MEYERS presented this patient, a girl, 18 years old, who had diminutive hands and forearms, with muscular weakness and want of muscular control in the upper extremities, together with absence of tactile, painful and thermal sensibility in the hands and in parts of the trunk corresponding to the distribution of the fourth and ninth dorsal nerves. While the patient had little of the ordinary use of the upper extremities she could write well and she had advanced to the second year of the high school. The reflexes in the lower extremity were preserved, but not increased. Labor had been prolonged, delivery was instrumental and the child appeared asphyxiated at birth and was with difficulty resuscitated. The conditions noted had been observed from earliest infancy.

Left-Sided Paralysis of the Extraocular and Intraocular Muscles, with Atrophy of the Left Optic Nerve.—Dr. FRANCIS X. DERCUM presented this patient. The case occurred in a married woman, 35 years old, who, following an attack of influenza, had occasional pain in the face and headache, with ptosis and immobility and some protrusion of the left eye and loss of vision on the same side. The Wassermann reaction was negative, and x-ray examination failed to disclose a lesion, as did also careful intranasal study. Slight improvement followed ascending doses of potassium iodide. The condition was thought possibly due to a retrobulbar lesion, although the long duration of the symptoms was difficult to explain. The possibility of thrombosis of the cavernous sinus also was considered.

Dr. JAMES HENDRIE LLOYD presented the brain obtained from the body of a patient who had been presented at an earlier meeting as one of sensory aphasia of traumatic origin. The patient was a man who was reported to have been run down on the street by a motor truck, suffering in consequence an injury over the left brow, and in whom x-ray examination disclosed the presence of a fracture of the basilar plate of the frontal bone on the same side. The man appeared to be word-deaf and word-blind, and he exhibited agraphia, astereognosis and right lateral hemianopsia. There was no motor aphasia, but an improper use of words, a form of paraphasia. At the outset there was no hemiplegia, but in the course of the disease right-sided motor weakness developed, while, later, stupor set in, and death took place. At post-mortem examination a new-growth, exhibiting the histologic characters of an endothelioma, was found in the white matter of the occipital lobe, and in the frontal lobe a second lesion suggestive of hemorrhagic softening. It seemed likely that the patient, seeing badly as a result of his hemianopsia from the new-growth in the occipital lobe, had been struck by the motor truck, the results of the injury thus produced consisting in the fracture at the base of the skull and the lesion in the frontal lobe.

Ocular Palsies of Apoplectiform Nature During an Attack of Severe Coughing.—Dr. ALFRED GORDON presented this case. The patient was a child about five years old, who at the age of three months, following a violent paroxysm of coughing, in an attack said to be bronchitis, developed paralysis of both external ocular recti muscles and of the left internal rectus. The eyes were crossed and there were also nystagmiform move-

ments. Although the Wassermann reaction was negative, improvement followed on administration of potassium iodid and went on to almost complete disappearance of the abnormal manifestations. It was supposed that as a result of the violence of the cough during an illness that might have been whooping-cough hemorrhage took place in the brain, perhaps in the region of the corpora quadrigemina.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

POCKET FORMULARY. By E. QUIN THORNTON. 292 pages. Price, \$2.00. Published by Lea & Febiger, 706 Sansom Street, Philadelphia.

LECTURES ON MEDICINE. A Handbook for Nurses. By CHALMERS WATSON, M.D., F.R.C.P.E. 295 pages. Price, \$1.75. Published by William Wood & Company, New York, 1918.

THE RELATION OF DRESS TO HEALTH, WITH SPECIAL REFERENCE TO THE ARMY UNIFORMS.

BY WALTER B. JAMES, M.D.,

NEW YORK.

THERE has been so much discussion and criticism of the various modern army uniforms that the writer is led to offer the present very modest contribution to the subject of dress, solely from the point of view of the physician, and from the belief that the importance of dress in its relation to health has never been fully appreciated either by the general public or by the medical profession.

We seem to be approaching, or even to have reached, a period when the conventions and traditions that have held us in so firm a grasp are being broken through; and when freedom of thought and freedom of speech, and common sense, and, above all, science, which after all is only knowledge, are more and more determining men's actions.

It is only a little while ago and within the recollection of most of us that a woman who appeared in trousers was liable to arrest, and even the modest bloomer attracted a hooting crowd. Today, in Europe, women, when it suits the requirements of their labor, wear the garb of men without attracting the slightest notice.

If the conventions of dress are to be broken down, and especially the conventions of military dress, it is wise that men should be guided by all the experience of the past as well as everything that modern science can teach. The book of clinical or practical experience is one of the hardest of all to read, and can be read correctly only when it is seen from many different angles, and the following few practical observations are presented, hoping that they may throw a little light on some of the phases of this difficult subject.

In his interesting and valuable book, "Civilization and Climate," Ellsworth Huntington proves that the general impression that people who live in so-called "even climates" are inefficient is justified by the facts, and by a long series of studies in anthropology he demonstrates that the effectiveness and general productiveness of a race is proportionate to the storminess of the climate in which it dwells.

The writer ventures to suggest the following physiological explanation of this fact:

The blood may be regarded as the immediate source from which comes the body's energy. In other words, it contains the fuel supply. The vasomotor nervous system, with its universally extending nerve fibers regulating the caliber of every

artery in the body and controlled from a central point, may be thought of as the operating department which determines the amount of blood that shall be in any organ or structure at any given time, so that it corresponds very closely to the operating department of any manufacturing or transportation system in commercial life.

The blood contains not only all the sources of energy, but also all of those agents by means of which the body combats the infections which produce so many of its diseases. Thus, both for the greatest energy and effectiveness of any organ, as well as for its successful resistance to disease, it is necessary that this operating department be maintained at its maximum of vigor and efficiency.

Changes of atmospheric temperature are met by corresponding alterations in the distribution of blood in the body, so that there shall always be a state of balance between each part of the body and the air which is in contact with it, and this is brought about and controlled solely by the vasomotor system. Just as an army can be kept efficient only by constant and continued drilling, and just as ocean travel can be kept safe only by the faithful performance of boat and fire drills, exercises that must be carried out almost daily during periods of great danger, so the human vasomotor system can be kept quickly and accurately responsive to call only by constant exercise and training.

The importance of congestion as preceding or forming the first stage of inflammation has long been recognized. It is at least possible, and indeed it seems likely, that congestion of a structure, a mucus membrane for instance, may render it susceptible to an attack of microorganisms previously existing there but unable to produce an inflammation as long as the circulation was normal.

Many years ago it was proved that a healthy peritoneum withstood an injection of bacteria which in the presence of a previously inflicted injury resulted in active peritonitis.

It seems fair to assume that with sudden atmospheric changes, and with the accompanying rapid changes in the distribution of the blood, it is the vasomotor system that must be relied upon chiefly to prevent local congestions.

It is by exposure of the surface of the body to changes of temperature that this vasomotor system can best be exercised, and this probably is the explanation of the value of hydrotherapeutics, especially the use of the Scotch douche, or rapidly alternating jets of hot and cold water to the spine. It is also probable that it is at least in part the reason for the usefulness of the so-called "sun cure" for tuberculosis at Leysin, for the Kneipp cure with its barefoot walking in the wet grass, and putting on thin linen underwear after a cold bath, without drying the body, for the open-air

treatment of tuberculosis, for the value of wet packs, and for the general invigorating effects of the cold bath.

Man had his origin in an environment that subjected him to frequent, rapid, and extreme changes from heat to cold, and from dryness to dampness; and from a study of his anatomy and physiology as well as from the teaching of the Law of Weismann, we know that we modern men are equipped with the same body device as were our Cromagnon progenitors. Weismann's Law is to the effect that acquired characters are not transmitted and its corollary is equally true, that unused or abused characters are not lost, so that we may think of all congenital characteristics, whether good or bad, as being entailed, and, as far as the race is concerned, as being permanent.

This explains why Helen Keller, the deaf and blind mute, was able to distinguish the colors of flowers by touch and why certain individuals when called upon in the course of their daily needs, discover rather than develop a sense of touch, of smell, or of taste rivaling that of the keenest scented animals.

Modern man is rarely if ever called upon for his protection to use a delicate sense of smell or of hearing, or even fleetness of foot, so that the failure to keep these in a state of training for immediate use is fraught with little if any danger. It is quite different, however, when we consider the protection from sudden temperature change through the operation of the vasomotor system, for while we can, as a rule, avoid such changes by artificial means, by clothing, and heated houses, for instance, yet a sudden alteration in environment nevertheless will occasionally occur, and then it finds nature's protecting apparatus napping.

A somewhat similar condition exists in food and diet. Modern methods of preparing and serving food secure the elimination of as much as possible of the rough and indigestible elements, as in the case of fine white flour, purees, creaming of spinach, and removing the skins of vegetables and fruits.

But the digestive organs of the man of today are the same as those of the cave man, and to preserve good digestion and good health insoluble materials are artificially added to the food, and the numerous advertisements of bran foods and other similar articles testify to the almost universally felt though not understood instinct to return towards the culinary conditions of our remote ancestors.

There is some reason for believing that the refinement of modern so-called civilized dress having its origin in tailors has somewhat the same bearing upon catching cold and other respiratory diseases that modern methods of preparing food and originating with cooks have upon the so-prevalent indigestion and constipation.

By living in an even climate, by living in overheated houses protected from drafts or temperature variations, and by protecting the skin from the air by close-fitting garments, one secures a maximum of sluggishness and inefficiency on the part of the vasomotor system and hence inefficiency on the part of the circulation generally.

Herein lie the dangers of the prevailing custom of overheated American homes, to which is added the peril of the various mechanical devices to se-

cure an unvarying temperature within doors. Nowhere is this better shown than in the prevailing overheating of railroad cars, especially Pullman cars and dining cars, where the regulation of ventilation and temperature is left to one whose origin in the Dark Continent renders him especially unfit to decide such questions for Caucasians. It is interesting to note that Ellsworth Huntington discovered that the efficiency of piece workers in factories in Bridgeport as measured by their output was directly proportionate to the violence of the temperature changes to which they were subjected. Benjamin Franklin ascribed much of his vigor to the air bath which he was in the habit of taking as part of his toilet.

There is little doubt, so far as health and body vigor go, and leaving all other considerations out of account, that the best modern costume for men ever designed by a civilized people is the Highlander's kilt, with its bare knees and thin trews.

It is a familiar observation in almost every family that most of the colds occur among the male members. There are few families in which the father has not preached into unwilling and entirely unresponsive ears that women by their so-called "irrational" methods of dress were risking their health and lives.

Women's dress takes no note of season, time of the day, or climate.

The question whether thin slippers or high boots, thick stockings or openwork, a cloth or a chiffon dress, high neck with a feather boa and close fit wrists or low neck and bare arms, fur or cloth hat or bareheaded; all of these questions are decided solely by the occasion and never by the season or the weather. The fact is, it is a familiar observation that women are superior to weather, while men are its slaves.

In spite of the claimed absurdness of women's dress, colds and catarrhs are for the most part maladies of the other sex, and pneumonia and bronchitis are certainly no less common, and indeed are probably more common, in men than in women; that in every family it is the men and not the women who make whatever disagreeable throat and nose noises are heard about the house; and that the cuspidor is masculine and not feminine. It is only necessary to note the size and character of the woman's pocket handkerchief, as compared with the man's, and the woman's scanty need of it, except as a trinket, as compared with her husband's slavish dependence upon it, to convince one that as far as the upper respiratory tract goes the so-called irrational dress of women has few if any apologies to make.

The present fashion of abbreviated skirts has been attended with no increase in throat maladies among its devotees, and there is good reason to believe that as the daytime dress of the sex approaches more and more closely to that of the Scotch Highlanders so will they in their bodily vigor and resistance to the weather approach more and more closely to that most hearty and vigorous of all people. Indeed, on the ground both of practical experience and the teachings of physiology it is to be hoped that as women come to take over more and more of the activities that man has heretofore monopolized they will not slavishly adopt his entirely irrational costume, but will, if they find it

necessary to make a change, adopt one devised on the ground of modern science and not selected for them by dressmakers and tailors, and that they will secure at least as free an exposure of the skin to the air as they are enjoying at present.

So irrational are the dictates of convention that the writer has heard on the tennis court objections raised to a male player's opening the first button or two of his silk shirt on the score of indecency by women who a few hours later after nightfall would appear in dress that left but little of the trunk unseen, so illogical are the dictates that have determined our dress, and in spite of the fact that there is so close a relation between dress and body health.

It is by no means a rationally thought out desire for health that determines women's dress, but purely a desire for admiration.

"Give unto me strange beauty, cried the young maid,

"More fair than all to be,

"So I anoint my body and go forth

"To draw men's souls to me."

It is chance, therefore, that has given to modern women the healthiest of all costumes, and it is to be hoped that apish imitation of men will not lead the other sex to adopt their irrational and unhygienic mode of dress.

There can be no doubt that a considerable part in the improvement in infant mortality statistics in modern times has come from more rational views of infant dress. The change from the swaddling clothes of a century or more ago to today's pleasing picture of the infant from birth on kicking its bare feet and legs free in the air has had great value in increased bodily vigor and resistance to disease in early life.

The father of Edward Gibbons, the historian, found it necessary to give to each one of five successive sons born to him the name of Edward in order to secure the transmission of that family patronymic, and Anne, Queen of England, was unable to leave an heir to the throne although she had given birth to either eighteen or nineteen children.

The fact that all insurance companies regard the expectation of life, after the age of 50, as better in women than in men, and that they base their rates upon this, would not encourage the view that women's dress was less hygienic than men's.

Only slavish subservience to the dictates of an entirely uninformed and unthinking group of tradesmen in whose hands rests the absolute decision of what men and women shall wear, brings it about that upon reaching a certain age we males must return towards the swaddling clothes of an earlier period while our sisters are permitted to go on for the rest of their lives with rational bodily covering.

The importance of the relation of the skin to the surrounding air is borne out by what we have learned in recent years of the principles of ventilation. We now know that the lassitude, headache, and depression that result from being in a poorly ventilated room are caused, not by breathing poisoned air, but through the influence of such an atmosphere upon the surface of the body. The principal factors that make for good ventilation are dryness, motion, and coolness of the atmosphere, while it is stillness, moisture, and heat exerted upon

the skin that produce the above uncomfortable symptoms. These same elements are probably those that are most effective in climate, together with variations of temperature.

But nowhere is the irrational in dress more striking than in military life. In private life, excepting for fashion and modern police requirements, every man is at liberty to dress as he wishes. In the army his dress is determined for him without any choice on his part. It might therefore be thought that here a broad view would be taken of the matter and the plain teachings of practical experience as well as the dictates of modern science would be given consideration. Such, however, as far as the civilian observer can see has not been the case. Military tradition and a desire to look different from other armies seem to have been the determining factors.

The chief points in the army uniform that seem not to be in accord with the principles before demonstrated and which prevent free contact between the skin and the air, which is necessary for health, resistance to disease, and for efficiency, are the closefitting woolen and often padded coat which must always be kept closely buttoned; the high closefitting collar; the woolen puttees resembling the bands in which the legs of infants were swaddled in a former and more barbaric age; and the regulation which necessitates the constant wearing of the hat or cap when out of doors. The modern soldier is almost hermetically sealed from the soles of his feet to his chin.

It is a question whether the raggedness and unkemptness of Washington's heroic little army during that melancholy winter at Valley Forge was not a better preparation for the spring encounter with an enemy more numerous and better equipped than themselves than would have been a cosy winter in a steam heated cantonment clad in the swaddling clothes of the modern fighting man.

From the point of view of modern science the clothing of the navy is far more rational than is that of the army, at least as far as the man of the line is concerned. It would be interesting to know whether the health of the former is less good than that of the army. The open front blouse and the bell-bottom trousers flapping in the wind secure at least a moderate exposure of some part of the body.

These thoughts suggest the old familiar and probably apocryphal reply of the Indian to the white man, that he did not catch cold in his nakedness because "Indian was all face."

An infectious disease requires for its development two elements, first the infecting agent and second a suitable soil, that is, a body or an organ with inadequate resistance. Is it not possible that in the endeavor to discover the origin of the numerous cases of pneumonia and other respiratory diseases that have occurred in the various army cantonments during the past winter too much attention has been paid to the infecting agents and too little heed has been given to the more common and obvious feature of the resisting powers of the men?

We have taken thousands of young men from civil costume and have swathed their limbs in puttees, clothed their bodies in closefitting woolen jackets, close buttoned to the chin, and so, changed completely the relation of their skin to the outside

air. In this respect we have made their dress differ even more than in civil life from the dress of woman.

We have put them into garments from which any doctor with wide experience and common sense would remove a young person as the very first step towards overcoming a tendency to catch cold.

Benjamin Franklin knew the value of a cold air bath night and morning, and the boys of our schools and colleges all know the delights and the health inspiration that come of going bareheaded and scantily clad in the coldest winter weather.

The Romans put their fighting men into a short tunic with bare legs, and this, although their operations were carried on in Spain, Germany, and Britain, and during centuries when, as shown both by physiography and geology the climate of southern Europe was a far stormier and more rugged one than at present.

The writer fully realizes that there are other and more important considerations that must be heeded in the army besides health, but he feels that the selection of the uniform has generally been made without a broad study of all the points bearing upon it, and the present modest contribution to the study of dress is offered only in the hope that it may direct attention to one of the little things that make for the health, comfort and efficiency of our soldiery.

7 EAST 70TH STREET.

THE TERATOLOGICAL COLLECTION OF THE ARMY MEDICAL MUSEUM *

By R. W. SHUFELDT, C.M.Z.S.,

MAJOR, MEDICAL CORPS, U. S. ARMY.

WASHINGTON, D. C.

CONSIDERING the little practical value that a knowledge of teratology has for the surgeon or the physician, it is certainly very remarkable what an enormous literature there is upon the subject, including its more or less nearly related branches. This applies to the medical and surgical literature of all nations; and the reason that it is so, seems to be based on the fact, that those of the profession, of every country, possess the trait common to all writers—the unquenchable desire to dwell upon and describe the unusual and the marvelous in nature.

As far back as we may delve into medical literature, we meet with an endless array of titles in our library catalogues of books, papers, and monographs devoted to descriptions of the various forms of monsters, and to the supposed causes of the monstrosities they present. Then, too, not only are these abnormalities to be met with in our own species; they occur in the case of all organic forms, as well as throughout the vegetable world. In the case of the latter, examples may be seen in flowers, leaves, seeds, and seed-pods, and similar structures, and frequently these are very remarkable. As in the vertebrate series, plants present deformities having the nature of suppression of parts, as well as of distortion and duplication. The malformations of plants, however, and the various causes producing them, form a very large subject—one not to be touched upon in the

present article. This applies, too, to such cases of teratology as have been discovered among the invertebrata—for instance among mollusks, insects, crustaceans, spiders, and other groups. As an example among thousands of others, the double claws of lobsters and crabs may be mentioned.

In so far as the Vertebrata are concerned, teratological deformities are of many kinds. Notwithstanding this, it would seem that, up to the present time, a fitting descriptive term has been given to each and all of them. Where the vice of conformation is very marked, exhibiting deformities of an extraordinary nature, the individual has, in the vernacular, been designated a "monster." Thus teratology is a science that takes into consideration the study of monsters and the causes leading to their production. In the opinion of some, the field, thus limited, would not include such departures from the normal as we find in hermaphroditism, for example, or in polydactylism; it is claimed that individuals presenting such peculiarities are not "monsters." In the main, however, it would seem to be more practical and less confusing to include, within the sphere of description of monstrosities,

FIG. 1. *Thoracopagus parasiticus* (Path. series, No. 8894). Female; 5 months old. Cast.

all forms of life, whether animal or vegetable, and to have the term teratology designate the science as a whole.

Several theories have been advanced to explain how these departures from the normal forms are produced—that is, what causes them. Perhaps of all these theories, the most widely accepted is, that each and any one of them has come about through some accidental change, which change has affected the fetus, with greater or less profundity, at some time during its existence *in utero*. There are still a few who entertain the opinion that, prior to birth, vertebrate animals—the human fetus included—are the victims of mental shocks of various kinds, shocks which are primarily received by the mother during the period of gestation, and which produce the several kinds of malformations we find in the young at birth. Classed among such disturbances of the mind of the mother, we find perversions of the imagination; frights of various kinds and degree; profound sexual excitation, and the like. Many interesting instances might be cited, apparently sustaining such a theory. Finally, the opinion has been advanced that all such monstrosities,

*Read at a meeting of the Biological Society of Washington, Jan. 26, 1918.

in so far as the vertebrata are concerned, are due to some primitive defect in the germ or ovum. Researchers in this difficult field of enquiry meet with no end of perplexing questions, in the matter of correctly demonstrating exactly the mode of action

FIG. 2. Thoracopagus. Lamb; male. (Path. series, No. 12965.)

of the aforesaid "accidental changes"; the nature of the "primitive defects," and the maternal mental disturbances.

Finding it difficult to attribute polydactylism—or the presence of supernumerary fingers or toes, or both—to any of the above causes, it has been held, and is still so held by many, that such abnormalities are primarily due to an excess of formative action in the parts so affected; but why such an excess takes place, in any individual case, is an extremely difficult question to answer.

Such deviations from the normal are now classified under the term *diplogenesi*s,—that is, where there happens to be a duplication of parts, or, in extreme cases, of entire individuals, the latter being classed under "double monsters" of the Siamese twins variety. These are explained through the theory of fusion—that is, two duly impregnated germs have become fused. As development proceeds, it results in one of the many forms described and referred to the diplogenic group of monsters.

As to the terminology used in the description of the various so-called monsters or other teratological types, it has become quite extensive; only such parts of it as are required in describing the specimens in hand will be employed or defined here.

With these few prefatory remarks, we may proceed to notice such teratological specimens as now form the collection of material of that class in the Army Medical Museum of this city. Many years have passed since the initial specimens of this collection were first placed in the exhibition cases in the old Ford's Theatre building on Tenth Street—a structure long known after the War of the Rebellion as the Army Medical Museum, and which, during that time, harbored the priceless medical library of the Surgeon General's Office. When the present Army Medical Museum was completed and ready for occupation, the museum and library was moved into it, the specimens constituting the former being cased and otherwise placed on exhibition in the hall designed for that purpose. In passing, it may be said, that this exhibition hall, and one or

two other small exhibition-rooms in the building, have, years ago, been stocked with the material constituting the collections of this institution to their utmost capacity, so that a more or less static condition of affairs has prevailed there for nearly a quarter of a century,' during which period hardly any material of a teratological nature has enhanced that section of the museum. Up to within a few years, little or nothing had been published about the specimens here to be noticed, when Dr. D. S. Lamb gave us his excellent brochure on the subject, with its illustrations.' As that appeared only five or six years ago, it is not likely that any startling additions have been made since its publication. In one of its leading paragraphs it is stated that the purpose of the contribution is to "present for consideration a summary of the malformations assembled in the Army Medical Museum. It will be interesting to know that there is so large a collection of malformations in a museum in this city,

FIG. 3. Dicephalus dibrachius. Male fetus. (Path. series, No. 14621.)

nearly 400 specimens, and that about one-third of these have been contributed by members of the Medical Society of the District of Columbia. These specimens, taken together, include nearly all possible forms. They are arranged according to the

well recognized classification of Foerster, as partly modified by Hirst and Piersol" (p. 35).

It would appear that there are no examples of *Situs transversus* in this collection, nor one of true human *hermaphroditism*—a condition that Doctor

FIG. 4. Hydrocephalus in a calf. (Path. series, No. 9923.) Cow died during parturition.

Lamb seems to question. A year after his paper appeared, however, such a case came to light, and an account of it was duly published.³ Partial *hermaphroditism*, however, has been met with in the vertebrata below man, and one such case at least is to be found in this collection. This is of a ten-months-old pig, wherein the external genitalia are female, all but the testes, which latter are present. The vagina and uterus are absent.⁴ We also find in this collection valuable and interesting specimens, in fine state of preservation, of *phocomelus*, of *sympodia*, *sirenomelus*, *celosoma*, *craniorachischisis*; and, in the case of the last malformation, we find specimens of *anencephalusism*, *pseudencephalusism*, and *exencephalusism*—that is, cases wherein the skull alone is involved in the deformity, the spinal cord and spine being normal. With respect to the specimen here shown in Fig. 7, both

FIG. 5. Hydrocephalus in an infant. (Path. series, No. 14481.) Skull, right lateral view.

skull and spine were involved. In other words, this fetus was not only *anencephalic*, but in addition presented a marked case of *spina bifida*. The physiognomy has a peculiar simian aspect about it—in so far as the skull bears it out. This malformation

is occasionally met with among vertebrates far down in the scale; this is exemplified in the case of an iguana in the museum's collection. Occasionally an adult may be normal in all respects, and a single azygos organ bifid. Possibly there may be such examples in the collection now being described.⁵

With respect to specimens exhibiting *hydrocephalus* in its various forms and at different times of life, from the earliest recognizable stages of fetal existence to individuals past middle life, there is to be found in this collection a very valuable series of specimens of our own species as well as of animals lower in the scale, especially of calves (*Bos*) of the

FIG. 6. Fetus at term. (Path. series, No. 9066.) Celosoma, hydrocephalus, agnathus, perobranchius, club-foot, displaced and adherent ribs; also thoracic-abdominal eventration. Lived a few seconds.

domestic cow. Some of these examples are very remarkable, and their histories, so far as known, quite unique (Figs. 4 and 5). In the case of the calf here shown, the cow died during parturition,* and

*This seems to be the usual outcome among domesticated cattle. Many years ago, while out hunting on the plains of Wyoming, near Fort Laramie, I came across a cow in labor. Examination disclosed the fact that the calf had a double head, and all my attempts at delivery failed. There is every reason to believe that the animal died that night, and I was not able to return to the place until three days thereafter. The wolves and coyotes had done their work, and the double head that I very much desired to secure was gone.

this may be the unhappy ending in mothers of our own kind.

We also have in this collection instructive examples of *meningocoele*, *meningo-encephalocoele*, and *hydroencephalocoele*, which are conditions generally con-

FIG. 7. Six months' fetus; anencephalus and spina bifida. (Path. series, No. 14478.)

sidered as falling in the category of teratological specimens.

A remarkable case is here shown in Fig. 6, it having been contributed to the collection by Dr. Geo. A. Hardin, of Sault-Sainte Marie, Michigan. When presented, the specimen was given the number of 9065, it being a human female infant with a large head, "eyes widely separated; ears likewise. Congenital fissure of anterior wall of thorax and abdomen, left side, with protrusion of left lung, heart, stomach, most of the intestines, and spleen. Right lung and liver and urinogenital organs normal in character and position. Left upper limb stunted and ending in 3 digits. Right foot shows talipes equinovarus." The skeleton was taken from this specimen (No. 9066, Fig. 6); in it "ribs are curved downwards, forwards, and inwards, lying almost flat against the spine; some are deformed in thickness and breadth, and two are united at their borders. First four ribs of right side united at their borders. The usual anomalies of hydro-

cephalus in the skull." Other deformities of skull are plainly shown in the figure. "Parents healthy and no deformity. Mother, Irish, age about 20."

Spina bifida is elegantly illustrated by numerous and varying examples, including those in which *hydrorhachis* is involved. These conditions are frequently associated with club-foot, harelip, and so on; and in these days, where the deformity is not too great, surgery does much towards rectifying it and saving the child. This subject will be touched upon in a future contribution.

Many of these malformations must have been well known to the ancients, among them the one-eyed monster, to which we now apply the name of *cyclops*. In fabulous history there is also a *cyclops*, one of the deities of Greek mythology; he was a great giant and supposed to possess a single, circular eye in the middle of his forehead. Among the fables of Norway we also have the single-eyed giant—there called a "troll"—and he was supposed to be able to remove it from its socket in the forehead. This eye was also luminous, and when it fell out through accident, the finder could use it to light his way in the dark forest."

The teratological specimens designated as *cyclops* technically belong in the class of *cyclocephalous* monsters, of which a fine example is given in Figure 2. (Wax Model.) There are many forms and variations of them, and the series is splendidly illustrated with rare specimens in the Army Medical Museum collection. This malformation varies in degree, from the well set single eye in the forehead, through several stages of great deformity; most of these have had terms applied to them designating the nature of the malformation."

Doctor Lamb states (*loc. cit.* p. 42) that "The eye is not always single; there are all degrees of approximation and fusion; the bones that separate the orbits are wanting. Of course the nose is absent, or there is only an apology for one in the shape of a tag of skin on the forehead [Fig. 12]. The explanation of the malformation is partly in the failure of the fronto-nasal process of embryonic life to develop and unite as it should do with the maxillary process. If this failure involves the structure of

FIG. 8. Skeleton of a canine puppy. Agnathus or absence of lower jaw; nasal bones and maxillae form a proboscis-like snout. (Comp. Anat. series, No. 2153.)

the face lower down, then the jaw is affected, either rudimentary or absent. In all these cases the ears are brought near each other and towards the lower part of the face."

Cyclocephalus also occurs in animals below man,

and this collection contains a number of interesting examples of it. Indeed, the student of this condition in general will find here much material to illustrate his researches.

At this writing there are three specimens in the

FIG. 9. Canine puppies exhibiting congenital absence of forelimbs,—that is, both are abrachia. Lived six weeks. (Path. series, No. 13200.)

collection exemplifying the condition as *omphalosite*. These are usually twin births, with one fetus receiving its blood supply through the normal maternal circulation, while the other has it from its twin by anastomoses of the umbilical and placental vessels. At birth, this latter fetus dies immediately; and is, as a matter of fact, terribly deformed and lacking in parts either wholly or partially. Such twins are known as *omphalosites* and *autosites*—the terms being self-explanatory.

Occasionally, the monstrosity met with is of much less extent, and when this is the case, the subjects are classed as *hemitera*; of these an extensive series exists in the collection, and they are seen to vary in several ways and in different degrees. (Figs. 8 and 9.) Their study is one of great interest, as they often explain the more complicated departures from the normal form. Should any of these types live to become of age, and the mental faculties are unimpaired, the deformity, from a medicolegal standpoint, in no way militates against any of the individual's rights as a citizen. For example, a man might be a marked hydrocephile; possess a multiplicity of digits on his hands and feet; his heart might be on the right side instead of on the left; he might have a harelip and clubfeet, together with a double uvula and like deformities—yet such a person would in no way be debarred from exercising any of his legal rights, such as are enjoyed by any normally constituted citizen at all times. In the case of such adult twins as the Siamese twins, the matter becomes more complicated, especially if they be so ligatured that death would follow the surgical attempt to separate them. In such a case, one twin might commit a murder, and be duly convicted in court; but to carry out the death sentence would result in deliberate murder of an innocent individual—the other twin. It would be interesting to know how a trial judge would decide under such circumstances. When such joinings are of the female sex, and they live to become of age, as did the Hungarian sisters, Helen and

Judith, equally interesting complications might easily arise, though of a different nature.

In this collection there is an extensive series of fine specimens illustrating the minor, or at least less grave malformations, and the victims do not legitimately belong in the monster class. Reference is made to such cases as absence of the pharynx, anomalies of the stomach and esophagus, also the intestines, which latter sometimes show diverticula, as Meckel's and so on; absence of the anal opening, of the liver and gall-bladder—there being absence of the latter in one specimen. Lobulation of the spleen is also exemplified in one or two specimens, and quite a long series of cases of accessory spleens—a condition by no means uncommon among negroes; one example presents no fewer than eight spleens. Doctor Lamb, in his long and extensive experience and practice, claims never to have met with a case where the spleen was entirely absent.

Anomalies of the heart are very numerous, and frequently interesting as well as important subjects for study. There is a remarkable collection of them in this museum, and they present nearly every phase of departure from the normal in the case of that organ. It is needless to state that it is never absent, though one of the lungs may be, as shown in the case of a seven months' fetus.

Owing to their marked frequency of occurrence, only the rarer examples illustrating anomalies of the veins and arteries, as well as the lymphatic vessels, have been placed on exhibition; but these are ample for the purposes of demonstration.*

*Dr. Samuel Busey, of Washington, paid in his life-time especial attention to the anomalies and physiology of the lymphatics (*Amer. Jour. Obstetrics*, Vol. X., p. 8, 1877). During the summer of 1875 I had the pleasure of assisting him in a long series of experi-

FIG. 10. Domestic fowl (*Gallus domesticus*). Case of dipygus. (Comp. Anat. series, No. 1139.) Dipygus parasiticus.

ments on dogs, wherein he cut off the lymph supply through ligation of the lymphatic duct at its termination. He added to the collection being described a remarkable specimen exhibiting congenital occlusion and dilatating of the lymph channels, which he described in the above cited article.

Space limitations prevent my mentioning, much less enumerating, the extraordinary series of specimens which offer examples of the anomalies of the urinary organs, the genitalia, the organs of respiration, of the nervous system, and many of those

FIG. 11. Ischiopagus tripus. Harelip. Female; junction by sacrum. One set of external genitals. (Path. series, No. 10059.)

of the skeleton, as for example the presence of cervical ribs, and so on. These are not only illustrated by valuable and interesting specimens as they occur in man, but likewise by a wonderful series of specimens chosen from all the other groups of the vertebrata, as fishes, reptiles,⁸ birds, and mammals.

Some of the most extraordinary examples of teratology are those referable to the class termed *terata catadidyma*, or where the monster exhibits a duplication of the superior moiety of the body, including the head; for the inferior half termed *terata anadidyma*. Where complete duplication occurs, we designate the resulting anomaly or monster as a case of *terata anacatydidyma*. As we know, there are subdivisions of all three of these classes, and one or both of the subjects may offer any number of the minor deformities, as club-feet, polydactylism, harelip, and the like, or even one or more of the major ones.

One of the most typical examples of *dicephalus dibrachius* is here shown in Figure 3. The subject is a male fetus at term, and it possesses a double head, double neck, and two arms. This monster was born about the 16th of November, 1914. It was a foot presentation, and lived only five minutes after delivery. Father and mother are Italians and residents of this country.

Double-headedness, with duplication of limbs and tail, is not particularly rare among the lower animals, even including fishes.* (Fig. 2.).

*Sometimes where lizards (and perhaps snakes) have their tails fractured off in some way, a double one will grow out to replace it. Such cases are distinct from teratological ones, and must not be confused with them.

This *diprosopus* is not uncommon in the calf of the domestic cow, and inclined to be still more frequent among cats. The museum has many specimens of it, as it is seen to occur in different animals.⁹ Sometimes the two heads of an animal, including man, are so differentiated that the cervical division of the spine, or even somewhat lower down the column, is duplicated (*dicephalus*). In rare instances, the duplicature is carried down to include the lumbar vertebræ as far as the sacrum.

"Some of these monsters," says Doctor Lamb, "live to adult age, as the Scotch brothers who lived 28 years, and the Tocci brothers who may still be living. The malformation is relatively common; the sex is twice female to once male. But the two individuals of each monster are always of the same sex." (*loc. cit.*, pp. 51, 52).

While the museum has two specimens of *ischiopagus* (Fig. 11), it does not possess a single example of the very rare malformation known as *pygopagus*. In the latter the sacrum and coccygeal vertebræ are joined. They are usually females; their mode of union holds them back to back, and they may—and usually do—live to a good age. The Bohemian, the North Carolina twins, and the Hungarian sisters, Judith and Helen, are all cases well known to the profession at large.

In the group *terata anadidyma*, the collection presents many deformed birds of the *dipygus* type, also of fish, dogs, and kittens (Fig. 10), but none

FIG. 12. Cyclocephalus. A cyclops. (One eye.) Path. series, No. 10098.)

of *Homo*. *Syncephalus* is more or less common, and consequently we find that the museum has some twenty-four specimens of it, four of which are human. Where the entire body is split upward to the head, it is designated as *craniopagus*; there are

some remarkable examples of it in this rich collection.

Equally interesting and instructive are the specimens exemplifying the assemblage called *terata anacatadidyma*. We find four specimens of the extremely rare monster designated as *prospothoracopagus*—that is, one joined to another by face and thorax; with the exception of the cervical region, which is broad, the vertebral columns are individualized. These monsters invariably die at birth.

Thoracopagus is by no means rare, and in them we find duplication of external as well as internal organs. (Fig. 2).

With respect to *dipygus parasiticus*, the collection contains a model of John Baptist dos Santos, and a photograph of the case of Louisa L. This latter individual had, attached to her pubic bone, a rudimentary pelvis, with two imperfect lower limbs. Curiously enough, she married and became the mother of two physically perfect children.

There are two examples of *thoracopagus parasiticus* in this museum, one being a male fetus which had gone to term. In it the exposed portions consist of an imperfect nose and ear, external to which there are the limbs, together with the shoulder, back, and pelvis. This parasite was attached to the anterior wall of the chest.* Another remarkable case of this character occurs in the collection as a fine cast in plaster (Fig. 1); it was originally in the Jeffries Wyman collection. It is of a female infant, nearly five months old, and perfectly normal—apart from the attached parasite. It was brought on exhibition from Canada to New York in 1858, being fatally attacked by pneumonia on the trip. It was a bright and vigorous child; and, through modern surgical methods, the parasite might possibly have been successfully removed. It is stated that the adventitious limbs possessed the power of movement. It was "joined apparently on the right of the sternum (but the deep junction is probably at the sternum). The head, neck, and most of the trunk of the parasite are absent; right shoulder and arm present, but the forearm is absent, and there are but three digits; below the waist all is as perfect and well developed as the host, except that the sex is not defined."

There is a limited series of unclassified specimens in the collection; but they do not all appear to be cases of true teratology.

Polydactylism, or multiplicity of the digits of manus and pes, are fairly well represented in this collection—for man as well as for other vertebrates. This condition is frequently hereditary, and in some instances may be attributed to reversion, as in the case of small lateral toes appearing in any of the *Equidæ*. In certain dogs, when these super-

*A number of years ago I examined a living case of this character; it was being exhibited in one of the side-shows of a circus at Washington, D. C. The victim was a man of about 25 years of age, handsome, and very dark skinned. He appeared to be an Indian (from India?), and was dressed as such. The parasite was entirely external, all but the head and upper part of the neck. It was as large as a child of 6 years, and perfectly formed. To the best of my recollection it was a male, and had the movements of a child in health. It was dark skinned, and rested on the man's lap. This case I described at a regular meeting of the Biological Society of Washington on the 24th of November, 1917. According to Doctor Lamb, Collaredo was a case of *thoracopagus parasiticus* (*loc. cit.*, p. 55).

fluous digits are removed, they will reproduce themselves."

A rare form of human polydactylism is here shown in Fig. 13; it is that of a double thumb. When a young man (in 1872), I met with a case exactly similar to this one in an Irish laborer. The thumbs were functional to the extent of having a pincer-like movement. Later, at an examination in physiology at Cornell University (Burt G. Wilder, Class of 1874), I drew such a hand to illustrate the question of polydactylism. At that time Professor Wilder claimed that no such case was known, neither "could there be such a case." He gave it as his opinion that I must be mistaken. The man had been under my observation for two years."

This brief account will give a fair idea of the animal abnormalities, monsters, and anomalies in the Army Medical Museum at the present writing.

FIG. 13. Polydactylus. (Double thumb.) (Path series, No. 8317.) Plaster cast from life.

To the student of such subjects as well to biologists, physicians, and general anatomists, it will be evident that examples of nearly every type of such departures from the normal may be examined here. They stand, however, sadly in need of scientific labeling and arrangement. The cases in which they are contained are out of date and crowded to the very limit of their capacity.¹² These deficiencies are not likely to be rectified until the New Army Medical Museum becomes an accomplished fact. As the plans for this latter are now finished, and the site for the building in Washington selected, it but remains for Congress to appropriate the sum necessary to proceed with the good work. The unrivaled library associated with this outgrown medical museum in the same building, demands more distinctly *immediate aid* than the latter. In it there is a superb collection of works on teratology.

Analogies Between Hydrophobia and Tetanus.—Remlinger shows that experiment brings out various analogies between these affections. When the latter are transmitted by means other than hypodermic and intramuscular injections, there is a period of latency with a sudden generalized development *d'emblée*. Both viruses may be swallowed with impunity. Autopsy lesions are similar in the two affections and in both death often occurs as a result of arrest of the heart's action.—*La Presse Médicale*.

SURGICAL HISTOLOGY AND ANATOMY OF THE BREAST.*

BY PARKER SYMS, M.D., F.A.C.S.

NEW YORK.

WHILE I have nothing new to add to the subject, it has seemed to me that a good deal of diversity of expression exists, and that I may be able to clarify certain points in a manner which will be of assistance.

A proper knowledge of the anatomy of the breast defining its dimensions and its relations to other structures is absolutely essential to the surgeon. Without it he cannot properly plan his operative procedure.

The same thing is true as to the histology of the breast; it is impossible for one to make a satisfactory study of the pathology of an organ unless one has very accurate knowledge concerning its normal structure. In no other organ of the body is this so essential as it is in the breast. The breast has such a variable existence and presents itself to us under such manifold conditions that it is necessary for us to have a thorough knowledge of its variations so that we may be able to judge when normality ceases

FIG. 1.—Section through normal breast illustrating nitric acid process of demonstrating breast tissue. (Harold Stiles.)

and just when abnormality begins. As far as the anatomy of the breast is concerned, we shall confine our considerations to the adult breast. As far as the histology is concerned we must study the breast during the period of the embryo, at birth, at puberty, during pregnancy, during lactation, in the resting state after lactation, and during the period after the menopause. We must study the evolutions which take place from one period to another and the involutions which take place from one period back to another, and of course the involution which takes

place after the menopause when the active function of the gland has ceased.

Anatomy: Harold Stiles of Edinburgh has given

*Read at the meeting of the Medical Society of the State of New York, April, 1917.

us what I consider to be the best description of the surgical anatomy of the breast, therefore I shall follow his text very largely. By means of his nitric acid test he made important discoveries which changed our previous conceptions as to the outlines and dimensions of the breast.

FIG. 3.—Sagittal section of the right mamma of a woman twenty-two years old. (Morris, after Testut.)

Treating the breast with 5 per cent. nitric acid as described by him brings out its component parts in strong contrast to one another, so that the parenchyma, the stroma, and the fat show very distinctly as tissue entities. By means of this test Stiles was able to show that breast tissue can be found far beyond the limits to which the organ was formerly supposed to be confined.

The breasts are two glands situated on either side of the sternum on the anterior aspect of the thorax. They are composed of the following elements:

1. Parenchyma.
2. Stroma, or connective tissue frame-work.
3. Fat, and of course, lymphatics, blood vessels, nerves, etc. The relative proportion of these elements will vary according to the individual, accord-

FIG. 4.—Cross section of the breast.

ing to her age, and according to whether or not the breast is functioning. We shall assume for our description the gland of an adult nullipara. The breast consists of (a) Corpus Mammæ, (b) Peripheral processes. These peripheral processes extend in

every direction. During the resting period they are insignificant, but during pregnancy and during the period of lactation they become fully developed, and compose a very important part of the organ.

Of course, these peripheral processes vary greatly in different individuals. There are three or four that extend toward the sternum; there is one that extends from the upper and outer quadrant of the gland along the axillary fold. This is usually the largest of them and has been called the mammary tail. Sometimes it develops in such a manner as to appear like a separate (supplementary) gland, but it is usually truly a peripheral process. A knowledge of these peripheral processes is of the utmost importance to the surgeon, and Stiles' description of them had a very great influence in developing the radical operation. These various processes are connected with one another toward their extremities by smaller processes which thus form a net-work. In the quiescent state these meshes are filled with fat lobules, but when evolution and development of the gland during pregnancy take place, the parenchyma increases at the expense of the fat which is absorbed,

FIG. 5.—Diagram showing dimensions of breast and relations to muscles. (Harold Stiles.)

so these peripheral processes add greatly to the size of the organ.

The corpus mammæ is variable in size, but in general terms it may be stated to extend from the second or third rib down to the sixth costal cartilage. At the level with the nipple it is about five inches in width, extending outward from near the border of the sternum. Two thirds of the body lie over the pectoralis major muscle. The outer and lower third lies over the serratus magnus muscle and some of the digitations of the external oblique.

The two breasts are never symmetrical in size and after the first pregnancy they never return to the virgin condition. With each evolution the structures of the fibrous frame work become stretched, its spaces become enlarged and the breasts become more and more pendulous so that a deep sulcus is formed under the lower margin. (The virgin breasts are compact and pyramidal, and have no such sulcus). Depending upon the individual, there is more or less

over production of fat. Sometimes the breasts become very large and prominent, but except in cases of true hypertrophy this is not due to an increase in glandular structure but of lobules of fat. Of course, when senile involution takes place the breasts become atrophic and shrunken in various degrees, according to the individual case.

Nerves: The nerves of the breast are derived from the 4th, 5th and 6th intercostal nerves. Sympathetic filaments from the thoracic cord pass to the breast along the intercostal nerves.

The arteries supplying the mammary gland are derived from the long thoracic branches of the axillary artery, and branches from the intercostal arteries and from numerous perforating branches of the internal mammary artery.

The veins form an anastomotic circle around the base of the nipple, called the plexus of Haller. The veins of the breast empty into the axillary and internal mammary veins.

In performing a modern operation for cancer of the breast, the surgeon is not much concerned with the intimate bloodvessels of the gland itself; the bloodvessels he is most interested in are those which supply the region and which are ligated and divided at their origin as near the axillary artery as possible. These are: the superior thoracic, the acromial thoracic, the alar thoracic, and the sub-scapular. The perforating branches of the internal mammary give one but little concern, and are not divided until the final ablation takes place.

Lymphatics: The lymphatics of the breast are too small to permit of dissection or of demonstration in their normal condition, and they are usually collapsed so they cannot be satisfactorily studied unless they are artificially or naturally injected. Langhans succeeded in injecting the lymphatics by means of a puncture in the interlobular connective tissue, by this means he distended a system of lymph channels forming a network in the stroma and enclosing one or more ultimate gland lobules in each mesh. This net-work receives lymph from the spaces between the acini and is continuous with lymphatics occupying the adventitious walls of the ducts which run parallel with these ducts toward the areola where they enter a plexus of larger lymphatics in the loose connective tissue surrounding the ampullæ or sinuses. This forms the subareola plexus of Sappey which communicates freely with the lymphatics of the nipple and of the surrounding skin. Much useful information as to the anatomical arrangement of the lymphatics has been gained by making a special study of these channels in cancer cases. Often one can gain a more satisfactory idea of the structure and arrangement in this way than by means of artificial injection. It was this kind of investigation which made the work of Handley of such great value.

Beside the lymphatics which are closely related to the parenchyma (the perilobular and periductal lymphatics) there are others which are more closely associated in their distribution with the blood vessels. These latter freely anastomose with the former. The larger bloodvessels are accompanied by two or more lymphatics occupying their sheaths.

As pointed out by Stiles, examination of a large number of breast cancers has shown the invasion of the lymphatic spaces by cancer cells, particularly:

"(A) In the connective tissue processes radiating from the tumor into the surrounding breast, or into the circummammary fat.

"(B) In the breast tissue remote from, as well as close to the tumor.

"(C) In the connective tissue septa which separate the circummammary fat lobules.

"(D) In the ligaments of Cooper, where they even convey cancer cells to the corium; and in the retromammary tissue and pectoral fascia.

"In the last named situation they are large and generally accompany the bloodvessels which pass to and from the deep surface of the gland. According to Sappey the lymphatics of the breast consist of: (A) A superficial or cutaneous set. (B) A deep or glandular set. He claims that all the trunks springing from the glandular system pass from the posterior surface and from the body of the gland toward the areola, where they form the subareola plexus which is made up of vessels of remarkably large size. From this subareola plexus pass two or three large trunks which empty themselves directly into the glands of the axilla."

Stiles does not agree with Sappey's contention that the two or three large trunks leading from the subareola plexus are the ultimate and only channels for the receipt of lymph from all parts of the gland.

According to Stiles, there are "Five sets of lymphatic vessels which communicate freely with one another. 1. A superficial or cutaneous set including those of the nipple, areola, and surrounding skin. 2. The subareola plexus of Sappey. 3. The intramammary lymphatics. 4. The lymphatics of the circummammary fat. 5. The retromammary lymphatics.

"The cutaneous and intramammary lymphatics in part open into the subareola plexus which connects these two systems. The lymphatics of the circummammary fat constitute a part of the general superficial lymphatic system of the thorax. They represent on the one hand, the lymphatics of the true skin and on the other hand the efferent lymphatics from the anterior surface and circumference of the mamma. These lymphatics of the circummammary fat open into the larger and deeper lymphatics placed between the layers of the deep fascia. Lastly, from the lymphatics of the deep fascia large trunks pierce its deep surface and constitute the well defined vessels with thin but muscular walls which pass to the lymphatic glands as their efferent vessels. The retromammary lymphatics, including those of the pectoral fascia, receive all the efferent mammary lymphatics which leave the posterior surface of the gland. In this way, therefore, the efferent lymphatics of the corpus mammæ, of the fat around it, and of the nipple, areola, and skin over it, open either directly or indirectly into the lymphatics of the deep fascia, which latter accompany the bloodvessels of the gland, pierce the deep fascia along with them, and so reach the lymphatic glands which lie in a group or chain alongside them. The lymphatics from the inner part of the mammæ accompany the perforating branches of the internal mammary artery to join the sternal glands placed along its trunk. The greater number, however, accompany the mammary branches of the acromiothoracic, the long thoracic, and the external mammary branches

of the axillary artery to open into the axillary glands."

There is also a communication between the lymphatics of the two breasts through a median anastomosis of both the superficial and of the retro-

FIG. 6.—Section through normal breast of still-born infant showing all the characteristics of an adult functioning breast. (Syms.)

mammary lymphatics. The main lymphatic trunks of the axilla run for the most part along the blood vessels.

The axillary glands after Quaine. "The Axillary glands are generally twelve or more, they vary much, however, in number as well as in their size in different individuals. From four to six are placed along the axillary vessels and receive the lymphatics

which ascend from the limb; four or five small pectoral glands lie further forward on the serratus magnus near the long thoracic artery, at the lower border of the pectoral muscles, and receive the lymphatics from the mammae and front chest, while three or four subscapular glands are situated at the back of the axilla along the subscapular vessels, and are joined by the lymphatics from the back. One or two small infraclavicular glands are also found immediately below the clavicle in the hollow between the pectoralis major and the deltoid muscles. They receive some lymphatics from outside the arm and shoulder and are connected above with the inferior cervical glands, below with the axillary glands. The efferent vessels of the axillary glands ascend with the subclavian vein, and form by their union in some cases a single trunk (axillary lymphatic trunk) in others two or three large vessels which terminate on the left side in the thoracic duct, and on the right side in the right lymphatic duct. Sometimes they open separately into the subclavian vein near its termination."

As a matter of fact, the description of these axillary glands as given in works on anatomy is neither accurate nor adequate from the standpoint of the surgeon. Stiles made a very illuminating study of this phase of the subject and pointed out the fact that in cancer cases one may find a great many more glands than the anatomies give account of, so that one may find twenty or thirty or even more. He showed that there are a great many glands so minute that they may be called latent until they spring into active existence, and he also showed that lobules of fat may often be transformed into lymphatic glands.

Before describing the minute structure of the breast, a word must be said about its life history,

FIG. 7.—Section through normal lactating breast; gland nodules are seen everywhere and fully developed. (Syms.)

FIG. 8.—Section through a normal adult inactive breast; gland nodules are few in number and small in size. (Syms.)

for this organ varies greatly in structure and in function during different periods of life of the individual. Throughout life it is the subject of constantly recurring evolutions and involutions.

At birth, strange to say, the breast is an active

FIG. 9.—Diagram illustrating William MacCarty's theory concerning mammary gland cells.

functionating gland, secreting milk. Within a few days, however, it relapses to the condition of a rudimentary organ; during childhood it simply grows as does the rest of the body; at puberty it takes on active but limited development; during adult life it changes but little until pregnancy occurs. It is only during the period of pregnancy that the gland becomes fully developed, and it is only during the period of lactation that the gland has an active function, and therefore a full development. After each lactation involution sets in and the gland returns to the resting state. After the menopause, the gland having ceased to have a use, the final involution sets in and the gland becomes atrophied in a manner peculiar to itself.

The breast is really an inverted portion of skin which has become highly differentiated into the formation of an active organ whose function is the secretion of milk. As this function is only called for after the completion of pregnancy, the gland naturally has a variable, and it might be said, transient existence.

Without going too deeply into the embryology of the breast, suffice it to say that the first anlage appears as a thickening of the narrow linear ectoderm which extends from the root of the anterior limb to the root of the posterior limb on each side of the body. In human embryos of 10 mm. on either side of the trunk is an epithelial thickening which extends from the root of the anterior limb to the root of the posterior limb. This is the mammary strand. The middle of this strand is known as the mammary crest. Posteriorly the mammary crest becomes obliterated, fading into a mammary band which finally disappears in the caudocranial direction. The mammary crest becomes shortened into the shape of a club or nodule which is designated as the primitive mammary bud (in an embryo of 23 mm. Bronha). The primitive mammary bud next plunges more deeply into the chorion which becomes condensed toward it in the form of a mesenchymatous nodule. The integument which surrounds the primitive mammary body undergoes at the same time a slight circular invagination which constitutes the anlage of the areola of the nipple. (Demonstrable in embryo at second month.) Later the mammary body becomes enlarged forming the glandular field

(Huss). From its deep aspect (5th or 6th month) sprout 20 to 25 epithelial outgrowths which are cylindrical or pear-shaped terminating in a club-shaped enlargement (anlagen of milk ducts, Bronha). These gradually become provided with lumen. At this stage the proliferation of connective tissue which surrounds the mammary bud terminates in the elevation of a prominent anlage, namely, the nipple. The result is the formation of a gland of very irregular type, which strongly suggests the general morphology and structure of the sweat glands.

When finally evolved the breast consists of an organ composed of a delicate fibrous frame work whose loose meshes separate and support the various structures of the gland. Beginning at the nipple there are the orifices of from 12 to 20 or more milk ducts or channels. In the neighborhood of the areola, these channels are expanded into ampullæ or reservoirs (milk sinuses). These milk ducts divide dichotomously until they terminate in flask shaped extensions which constitute the acini or secretory part of the gland. This gland is made up of lobules which grouped together form lobes, each series belonging to its own set and terminating in its own proper milk duct. The canals and the acini are surrounded by a definite basement membrane. On this membrane rest epithelial cells which are the true gland cells. In the larger ducts this epithelium is cylindrical but in the smaller ducts and acini it is cuboidal, and consists of a single layer. Besides these cuboidal epithelial cells there are to be found a few flattened cells between them and the basement membrane of irregular shape, and it is these latter cells which are the subject of a good deal of controversy, or at least of a good deal of difference of opinion. According to some authorities these are the basket cells, and according to some they are connective tissue cells. According to others they are muscle cells derived from the minute blood vessels.

MacCarty of Rochester has very decided opinions regarding these cells. He claims that they are really

FIG. 10.—Diagram illustrating William MacCarty's hypothesis as to the differentiated cells, and the cells of the stratum germinativum.

undifferentiated epithelial cells analogous to the basal cells of the skin. Under certain conditions, he claims, these cells take on a form of hyperplasia, displacing and replacing the true epithelial cells of the gland, and that it is these cells which become the

cancer cells when they take on a form of migratory hyperplasia.

Of course, besides the ducts and their acini (the parenchyma of the gland), there are the nerves, lymphatics, and the minute bloodvessels surrounding the ducts and the acini, and arranged into regular systems; there is the connective tissue frame work of the organ; there are nodules of fat everywhere except under the areola; there are undeveloped sweat glands and sebaceous glands, the glands of Montgomery. In the areola and nipple are some muscular fibres which give the nipple an erectile function.

The histology of the breast varies throughout life according to certain conditions. At the time of birth and continuing for five or six days the breast is capable of lactation, having been activated by the corpus luteum at the same time that the mother's breast was. Immediately thereafter the breast is found to be a rudimentary organ. The parenchyma which consists merely of branching cylindrical tubes embodied in an insignificant amount of fat. There are an undeveloped areola and nipple; the breast scarcely exists.

Throughout the years of childhood but little change takes place. At the time of puberty a decided change takes place in the breasts of both sexes. In the female this change is progressive and lasting. The milk spaces are amplified, distension takes place at the end of some of the ducts with the formation of acini. These are grouped in the formation of a lobule. This group of acini with their ducts are joined in the final milk canal and constitutes a glandular unit. With the occurrence of the first pregnancy evolution takes place, and the gland becomes an active organ. There is a great increase in the parenchyma by formation of a tremendous number of acini. These are formed by a process of budding and expansion. The lobules of fat which constituted most of the breast are absorbed and disappear, and the breast consists of an actively developed group of glandular units capable of great activity.

After lactation has ceased involution sets in with a diminution of the size and number of acini and with the rehabilitation of fat. With each pregnancy a similar cycle ensues.

With the occurrence of the menopause comes the final involution or atrophy. There is a diminution not only in the size, but in the number of the acini and ducts. In other words, there is a great reduction in the number of gland units. It is very essential that this should be fully understood. Concerning this there has been much misunderstanding and much misstatement.

This final involution of the breast normally consists of an atrophy of all the essential elements of the breast. One element may be more atrophied than another so that there may be a disproportion but there is no productive proliferation of any essential element of the breast. Such proliferation would constitute a pathic process—it would belong to the domain of pathology and not histology.

IS THE DIAGNOSIS OF THE PRECANCEROUS STAGE POSSIBLE IN UTERINE DISEASE?

By HOWARD CRUTCHER, M.D.,

TULAROSA, NEW MEXICO.

THIRTY years ago, after an earnest conference with an old and valued teacher concerning the prevalence and the deadliness of uterine cancer, I formed the resolution to devote my best thought and energies to the solution of one of the most difficult and vexatious problems within the whole range of practical surgery. It is no pleasing thing to have to record a long series of utter failures, and if pleasure were the only motive prompting the presentation of a medical paper the present writing would not be undertaken.

Not that I lament the years spent in devoted study and reflection, for, while not attaining the summit of the stately range I set out to surmount, I have at least arrived at some practical conclusions in the saving of human life and the prevention of human suffering.

There is really no such condition in practical life as a precancerous stage in uterine disease any more than there is a prefracture stage for a broken collar bone. Wedges of scar tissue in the uterine cervix, acrid discharges from the canal of that organ, prolonged engorgement of the tissues of that region are without question recognized to be dangerous factors in the development of malignancy, so often are they found to be associated with it, precisely as icy sidewalks, slippery streets, and a collection of ice skates bring to the mind fractured bones, but it is out of all reason to base the art of surgery upon speculative possibilities to the exclusion of a scientific groundwork. At one time, discouraged by a steadily rising death rate, I concluded that in every suspected case a section of the uterine cervix ought to be removed for microscopic verification, but this visionary and dangerous theory was never put into practice for the substantial reason that it was soon exploded by the luminous rays of unexpected experience of a most practical and overwhelming character.

Within a few months of one another two women, both between forty and fifty years of age, appeared at my clinic in Chicago, and were oper-

ated on for the correction of lacerations of the uterine cervix. So far as I now recollect neither patient presented anything material at variance with hundreds of other cases of the kind. In both patients the union of the wounded tissues was prompt and for a time all went well; but in both there developed within a year unmistakable indications of malignant growths. It is practically certain that I wounded cancerous areas without being conscious of what I was doing, and that the operative work in both cases hastened the development of irremediable complications; but it is also perfectly clear that in the light of later and decisive clinical experience, both patients ought to have been subjected to what would have been an early hysterectomy, which might have saved both lives, or at least greatly prolonged them. I do not know that I was greatly if at all to blame for the loss of these patients; I followed the usual practice, gained an apparent temporary success, and, I might add, reaped in the end precisely the result that is generally to be expected from piecemeal surgery. So strong is the influence of early teaching that it took me many years to learn, despite repeated warnings, that many so-called lacerations of the cervix are not confined to the limits of the cervix at all, but frequently invade the body of the womb in a most surprising manner. Long ago I learned that all rational uterine operations must be based, not upon some technical formula, but upon clear scientific principles, namely, the attempt aimed at the correction or removal of whatever pathological conditions may be found to exist. If troublesome or dangerous conditions are demonstrated to be limited to the area of the cervix and do not extend beyond that area, there is no rational ground for further operative invasion; but the surgeon must set up no fanciful landmarks to supplant the indications of sound pathological teaching. If the uterus itself is found to be damaged beyond hope of repair its removal ought to follow as a matter of course. During the month of June, 1905, while spending a day in intimate private conversation with the lamented Nicholas Senn I brought up the subject of uterine surgery as related to cancer, when that illustrious man remarked, "It is a most discouraging field because of the failure of early diagnosis."

It would be of deep interest to learn how many men of lesser fame than Dr. Senn have reaped discouraging results from their invasions of the field of uterine surgery without ever making an earnest and steadfast effort to analyze the causes of their failures.

As discouraging as it may sound, it may well be questioned whether a great deal of progress is possible in the realm of early diagnosis and for the plainest and most conclusive of reasons. Well women and those supposedly well certainly do not seek medical advice, and of those who present themselves with what all recognize as the classical symptoms of that disease in how deplorably small a number are we able to extend any well-founded hopes of ultimate cure, even following the most prompt and radical surgical measures. Nor can it be denied that many women who live in dread of cancer, dread still more the announce-

ment of the fact that the condition exists, and appear more determined to resist rational efforts for its cure than to offer the slightest resistance to the progress of the disease. One woman, the representative of a very large class, it must be confessed, calmly assured me that she supposed that she might live a year or so with the growth rather than take the small risk involved in an early and perhaps a life-saving surgical operation. Then, too, there are many abject simpletons who declare with calm exterior that, as they came into the world with a uterus, so do they feel it a moral duty to take it with them to their grave! Nonsense based upon this precious theory might be extended almost without limit. Even superficial students of history must have learned that millions of the human race have met with trouble, disaster, and even total ruin after the severing of their umbilical cords, and it would require the most reckless statistician alive to estimate even roughly the numbers who have perished from strangulation by the same ropy tissue without breathing a single time. Foolishness of this sort deserves nothing but contempt from thoughtful minds, but the more thoughtful the mind the more certain it is that its conclusions will be scornfully rejected by those who prefer folly to wisdom. And it must be remembered that countless laymen, even those who are gifted with a fair degree of general intelligence, universally associate the very name of cancer with certain death, so little do they know, or care to know, concerning the modern rational treatment of that disease. My own operative death rate from a long series of vaginal hysterectomies, many of them carried out for the relief of cancer, has been below 1 per cent., but in the minds of many a single death in a hundred serious operations only proves the immediate dangers of surgery and proves to them nothing else. Operated on and died, death from operation for appendicitis, dies after operation, and operation fails to save life, are some of the phrases more or less familiar for the past thirty years. Hundreds of years added to life, hundreds of years of useful existence prolonged, hundreds of years of suffering prevented, are all forgotten the moment some pitiable victim of intestinal cancer dies after a desperate midnight attempt is made to prolong a life in comparative ease when no degree of human skill could effect any result that could be called curative. But, in the face of all discouragements, the medical profession has but a single path before it and that path leads to incessant labor for improvement, both as to methods of diagnosis and the betterment of operative procedure, regardless of all that obstructs the progress of scientific truth. All intelligent Kentuckians of today glorify the works and fame of Ephraim McDowell, but the attempt of the Boyle County grand jury to indict him for performing what Sir Frederick Treves happily styles the "First deliberate abdominal operation in the world," is nearly or quite forgotten. McDowell lived, and lives, as did his patient live, and who, thanks to the undying fame of the illustrious surgeon, will always live as the woman who said, "I am ready, Dr. McDowell, you may go ahead!"

My conclusion is that a uterus that is neither more nor less than useless ought to be left alone by the surgeon; but that a uterus that adds distress and danger to uselessness, ought to be removed under proper conditions at the earliest practicable moment.

MOUTH SURGERY, WITH SPECIAL REFERENCE TO CYSTS OF THE JAWS.*

BY THEODOR BLUM, D.D.S., M.D. (PENN.); UNIVERSAE MEDICINAE DOCTOR (VIENNA).

NEW YORK.

DIRECTOR, DEPARTMENT OF ORAL SURGERY, NEW YORK THROAT, NOSE AND LUNG HOSPITAL, COLUMBIA UNIVERSITY, ADVANCED COURSES IN DENTISTRY; ASSISTANT PROFESSOR IN ORAL SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

MODERN mouth surgery developed with the introduction of local anesthesia. Previously, operations on the jaws or soft tissues of the mouth had to be performed mostly under a general anesthetic, the administration of which repeatedly interrupted the surgeon's work. The flow of blood obstructed the operator's view, and the necessary frequent sponging prolonged the duration of his work unduly. In this country especially, nitrous oxide in combination with oxygen has been most frequently employed of late in this branch of surgery. It does not permit the operator to perform his duty with as much ease and pleasure as one is used to when operating under local anesthesia. With the improvement of the technique of injection the technique of the different operations for the surgical diseases of the mouth has been modernized, mainly due to the fact that the cooperation of the patient and also the bloodless field of operation permit the surgeon to observe clearly, step by step, the progress of his work. The employment of local anesthesia for this work is so general at the present time that one need not go any further into detail as to its merits. The type of local anesthesia used is of the conductive variety ("nerve-blocking"), the method of which can be studied in previous articles on the subject written by the author. Practically all the surgical diseases hereafter mentioned can be operated on under conductive anesthesia.

A subject frequently heard of during the last few years is that of apical infections. Under so-called apical infections we understand the thickening of the apical peridental membrane, caused in nearly all cases by death and infection of the dental pulp. While in cases of systemic diseases it may be advisable to remove the offending teeth, and, of course, curet the apical areas, it is possible in a large number of cases to save the tooth by performing a root amputation, consisting of the removal of the apex of the tooth and the curetage of the apical area by an incision made through the gum tissue. Whenever possible, the root canal should be well filled before one proceeds with the surgical treatment. The success of the operation will depend upon the selection of the cases.

The chronic thickening of the apical peridental membrane may continue until, either through lack of blood supply or through pressure, the center of this so-called "granuloma" breaks down. If now

*Read at a meeting of the German Medical Society of the City of New York, February 4, 1918.

the cavity becomes lined with epithelial cells derived from the peridental membrane (glands of Serres), we are dealing with a radicular cyst, a cyst originating from a diseased root. These hollow tumors may continue to grow until they occupy the whole jaw, displacing important structures like the antrum in the maxilla or the contents of the inferior dental canal in the mandible. The cyst wall is made up of a fibrous capsule, and lined, as said before, with epithelial cells. The cavity may be empty, or filled with a serous fluid, cheesy material, calcareous concretions, pus, or serous fluid rich in cholesterin crystals. The contents of a cyst are usually sterile, except when through some external interference a secondary infection takes place and pus is formed.

Radicular cysts occur most frequently between the twentieth and thirtieth years. They are apparently more frequent in the maxilla. One of the most important symptoms is the parchmentlike crepitation elicited upon pressure over the thinned out and distended outer plate of bone forming the outer wall of the cyst. The condition is diagnosed without a doubt by means of the x-ray. The treatment is, of course, surgical—conservative or radical. The radical procedure consists of the entire removal of the cyst membrane, which can easily be peeled off the surrounding bone with a curet or periosteal elevator. The sharp edges of bone and the overhanging soft tissues are smoothed down and the wound painted with iodine, and then packed with novocain, orthoform, an iodoform gauze. The healing takes much longer than in the conservative treatment, which differs in the following: After making an incision through the buccal soft tissues the flap is retracted and the outer half of the cyst membrane, including the overlying bone, is removed in such a manner that only a shallow inner cyst-half (including the cyst membrane) remains. In this way a circular wound is left to granulate, and even part of this wound may be covered by suturing the periosteum and overlying soft tissues to the membranous cyst wall. The wound is packed a few times with iodoform gauze, and thereafter taken care of by the patient, who syringes the cavity after meals. Finally it flattens out entirely and is hardly noticeable. The cyst membrane changes into one which is practically identical with the mucous membrane of the mouth. (Partsch.)

The follicular cyst is one originating from a tooth follicle. In it is found, therefore, an unerupted tooth or tooth germ. It occurs most frequently between the twelfth and sixteenth years. In symptoms and treatment it does not differ otherwise from the radicular cyst. Another important cyst formation is the so-called multilocular cyst. Its treatment must be absolutely radical because it is made up of many small cysts, each one of which may continue to grow if left in the jaw.

Of the solid tumors we find practically all varieties in the oral cavity. The treatment of all tumors, whether benign or malignant, is radical, meaning not only the early removal but also the extirpation of the same by making the incision well out into sound tissue without conservation of healthy neighboring teeth or bone. The operation for tumors of doubtful or malignant character should always be followed by x-ray or radium treatment. Good re-

sults have oftentimes been reported by treatment of inoperable cases with the above agents. The lymph glands draining malignant neoplasms must naturally be dissected out unless the case is seen very early.

A specimen for microscopic examination should not be taken before the operation, for fear that tumor cells may be carried at the time to different parts of the body (Bloodgood). The microscopic examination and diagnosis should be made by one familiar with oral pathology to avoid mistakes.

The odontoma, a benign solid tumor, found only in the jaws, must be mentioned here. It is made up of dental tissues—enamel, dentin, or cementum. They may be simple or composite.

Most of the bone infections of the jaws are caused by diseased teeth. Their treatment consists in free evacuation of the pus and the removal of the source of infection. In severe cases sequestra are formed, in the removal of which conservatism should prevail. A retained sequestrum will often prevent a pathological fracture or act as a splint until enough new bone is formed. Osteomyelitis is also found in children, following exanthematous fevers.

Of fractures, those of the mandible are by far the most frequent. They do not differ much in any respect from those in other regions of the body, except in treatment. The peculiar relation of the mandible to the maxilla allows us very often to use the maxilla as a splint for the mandible, and vice versa. The fixation of the fragments can be accomplished in an emergency with an ordinary bandage (Barton's), while later on wires, interdental, maxillomandibular splints, etc., may be employed. The most modern treatment, when applicable, consists of a sliding joint (Gleitschiene of Schroeder) attached to the maxilla and mandible, permitting the opening and closing of the jaws without any lateral motion. With this appliance the parts can easily be inspected, while the fractured ends receive that small amount of irritation which causes enough stimulation to hasten callous formation.

Wisdom teeth often play a very important part as etiological factors. Nervous disorders, local or reflex pains, trismus, etc., have been traced to unerupted, partly erupted, and infected wisdom teeth. Their removal can be performed under conductive anesthesia with comparative ease, and in practically all cases without the loss of the second molar.

Obstruction of the ducts of the submaxillary or sublingual glands causes a tumor in the floor of the mouth, which is known as ranula, and really is a cyst. Extensive cases are successfully operated on by employing the conservative treatment of cysts as described above. Salivary calculi, which sometimes are responsible for the formation of ranulae, may lodge in the gland structure itself or in the duct; their removal is, of course, necessary.

It is said that about two-thirds of all infections of the antrum are due to diseases of the teeth or surrounding tissues. In this instance the source of infection must be entirely removed, and the treatment in most cases carried on through the oral cavity. At times the infection may travel into the maxillary sinus without there being any direct communication between it and the diseased area, when, after removing the pathological tissue, the antrum can be washed out through the nose until the infec-

tion has disappeared. The odor of pus forming in the antrum through diseased teeth is, as a rule, more marked and foul than that caused by nasal infections.

The main object of this paper is to interest the medical practitioner in the possibilities of mouth surgery and to show the necessity of the existence of this specialty, as the treatment of surgical diseases of the mouth requires a knowledge of the special pathology of the oral cavity, not, as a rule, familiar to the general surgeon.

ABRAMS' METHOD OF TREATMENT OF ANEURYSM.

BY R. KODAMA, M.D.,

TOKIO, JAPAN.

DR. ALBERT ABRAMS of San Francisco first directed attention to his method of treatment of aneurysms in his work on Spondylotherapy.¹ Later, he reported in the *British Medical Journal*² and *La Presse Médicale*³ forty cases in his own practice of thoracic and abdominal aneurysm symptomatically cured within a few weeks by his treatment, with absolutely no other adjuvant measure, not even rest.

Snow,⁴ Jarvis,⁵ and others, show by a series of radiograms variations in volume of aneurysms superinduced by the elicitation of the aortic reflex of contraction (concussion of the seventh cervical spine). The Minerbis of Italy, Houlié in France, and other foreign writers, have also contributed to the literature on the subject.

Abrams' most recent observation respecting his treatment is as follows:⁶ "After the lapse of years, the enthusiasm of my early reports enables me now to conclude that in early cases the Abrams method is practically a specific, but in late cases all that can be achieved is a relief of symptoms, and that can be done more rapidly than by any other known method." His method has been fully described in his book on the subject.

My individual experience with the method is given in the report of eleven cases in my translation of Abrams' book into the Japanese language (1918). I shall briefly report these cases, together with others in this communication. The diagnoses in the following cases were confirmed by the x-rays, and the treatment consisted of concussion of the seventh cervical spine.

CASE I.—Cook, aged 61 years. Syphilitic anamnesis, negative. Symptoms during a period of two years; asthmatic, severe dyspnea on exertion, spasmodic cough. Aneurysm of the arcus aortae. All the symptoms disappeared within a few days after commencement of treatment and the patient has resumed his work.

CASE II.—Hotel proprietor, aged 49 years. Pains in the arm radiating to the neck with symptoms suggesting asthma. Asthmatic symptoms can be evoked at will by singing the Japanese song, "Utai" (which demands prolonged expiration). Diagnosis: aneurysm of the descending aorta. Results of treatment were not definite owing to the fact that the symptoms often abated without treatment.

CASE III.—Expressman, aged 49 years. History of syphilis at age of 26 years. Extremely dyspneic. Diagnosis at the University Hospital of aneurysm, but no improvement following treatment, he was discharged as incurable. My diagnosis was an aneurysm of the ascending aorta. Within a week, pulsations and dyspnea practically disappeared. The dullness corresponding to the site of the aneurysm was much diminished and the only subjective symptom remaining was a slight pain in the back contiguous to the scapula. Patient resumed his work and now comes from Yokohama for treatment once in two weeks to prevent a recurrence of symptoms.

CASE IV.—Tailor, aged 56 years. Aneurysm of the abdominal aorta. Had been treated for carcinoma ventriculi. During the x-ray inspection, compression at the 10th dorsal spine enlarged the shadow 2 cm., Dr. Abrams shows that stimulation at this paravertebral area will elicit the aortic reflex of dilatation. Duration of treatment, two months. It brought about a disappearance of all symptoms up to the present time of writing (1½ years) and patient was able to resume his work.

CASE V.—Housewife, aged 47. Recurrent pains in the back and abdomen necessitating the use of morphine. Aneurysm of the abdominal aorta. Symptomatically cured after treatment lasting three weeks.

CASE VI.—Banker, aged 45 years. Aneurysm of the abdominal aorta. All the symptoms practically abated after fifty treatments. Results were apparent after the first treatment. Slight occasional pain in the back is the only symptom which has persisted and at the present time of writing, he is symptomatically cured.

CASE VII.—Housewife, aged 49. Aneurysm of the descending aorta complicated by exophthalmic goiter. All the symptoms of both conditions disappeared under this treatment by concussion, which is also practically a specific in exophthalmic goiter as Dr. Abrams has shown.

CASE VIII.—Farmer, aged 40 years. The diagnosis of aneurysm was made in 1913. Four years later, the aneurysm was visible by direct inspection and measured four inches in the transverse diameter. Against the advice of his physicians, he traveled 100 miles to visit me in Tokio. Aneurysm of the ascending aorta was diagnosed. After the first treatment, the area of the protruding aneurysm was reduced fully one-third.

CASE IX.—Soldier, aged 38 years. Was discharged from the army during the Russo-Japanese war on account of an aneurysm of the ascending aorta. Dyspnea intense. After the first treatment, pulse was reduced in frequency from 90 to 70. Is now symptomatically well.

CASE X.—Miner, aged 48 years. The most pronounced symptoms of thoracic aneurysm. Diagnosis at the University Hospital of aneurysm. No relief from treatment. Began treatment at my hospital in December, 1916. He has resumed his occupation although there is some dysphonia and the Oliver-Cardarelli sign persists.

CASE XI.—Housewife, aged 52 years. Most pronounced symptom was dysphagia. Aneurysm of the thoracic aorta was discovered on examination. The dysphagia disappeared after the tenth treatment.

In addition to the foregoing, the following summary is presented of other cases of aneurysm which have come under my observation.

Name.	Age.	Chief Symptoms.	Result.
1. Mishikawa...	60	Dyspnea.	Symptomatically cured in two weeks.
2. Saito.....	47	Cough and pains.	Symptomatically cured in three weeks.
3. Nemot.....	36	Abdominal pains.	No results.
4. Suzuki.....	55	Dysphagia.	Improvement.
5. Nakayama...	57	Dyspnea and gastric symptoms.	Improvement.
6. Suzuki.....	48	Dyspnea and dysphagia.	Improvement.
7. Arai.....	73	Pains.	Symptomatically cured.
8. Yoshimura...	47	Dyspnea and pains.	Symptomatically cured.
9. Ito.....	72	Dysphagia.	Symptomatically cured.
10. Furuga.....	42	Dysphagia and dysphonia.	Too late for treatment.
11. Sato.....	50	Dyspnea.	Improvement.
12. Chilia.....	55	Dyspnea and pains.	Improvement.
13. Ito.....	45	Anginoid pains.	Cured.
14. Hozaki.....	42	Anginoid pains and dyspnea.	Symptomatically cured.
15. Suzuki.....	55	Anginoid pains.....	Partial recovery.
16. Matsusaki...	48	Gastric pains.	Symptomatically cured.
17. Suzuki.....	38	Dyspnea and dysphagia.	Almost symptom-free.
18. Suzuki.....	27	Dyspnea and palpitation....	Improvement.
19. Shiraiishi...	56	Paralysis of vocal cords.	Improvement.
20. Ota.....	42	Cervico-occipital pains.	Cured.
21. Moriyama...	56	Cough and orthopnea.....	Improvement.
22. Takahashi...	34	Pains and twitching (unilateral).	Cured.
23. Suzuki.....	36	Extreme dysphagia.	Too late for treatment.
24. Tarumi.....	51	Anginoid pains.	Temporary improvement only. Too late for treatment.
25. Yamamoto...	44	Anginoid pains and dyspnea.	Symptomatically cured.
26. Sakurai.....	45	Complicated by tuberculosis.	No treatment.
27. Takenoto...	42	Pains and palpitation.	Practically well.
28. Kitabayashi...	39	Palpitation.	Symptomatically cured.
29. Ota.....	56	Dyspnea.	Recovered.
30. Niesuma.....	50	Epigastralgia.	No improvement.
31. Iwabaki.....	69	No subjective symptoms of an abdominal aneurysm.	Reduction in size one-half.
32. Pakeda.....	38	Paresthesia in throat.	No improvement.
33. Muri.....	61	Paresthesia right hand.	Improved.
34. Nakada.....	54	Dyspnea.	Practically cured.

Medicolegal Notes.

False Statement to Medical Examiner as to Use of Liquor.—The Iowa Supreme Court holds that inquiries, in an application for life insurance, as to whether the applicant had ever used liquor, and in what quantities presently and in the past, inhered in the report of the insurer's medical examiner, so that false answers as to past use, in the absence of fraud on the examiner, were no defense to the insurer, under Iowa Code § 1812, providing that when the medical examiner of any life insurer shall issue a certificate of health, or declare the applicant a fit subject for insurance, or so report to the insurer or its agent, the insurer shall be estopped from setting up that the assured was not in the condition of health required by the policy. A report on an applicant for life insurance, made by the insurer's medical examiner by answers to questions as to the applicant's physical condition in numerous specified respects, is held to be such a report as is contemplated by the statute. The court quoted with approval from the holding of the Court of Appeals of Kentucky in *Mutual Life Insurance Co. vs. Thomson*, 94 Ky. 253, 22 S.W. 89, as follows:

"It is of vital importance for an insurance company to know, before issuing a life policy, whether the applicant is then temperate in his habits, for obviously he would not be a fit subject for insurance, nor could a company prudently issue to him a life policy, if he were not then temperate in his habits of drinking intoxicating liquors; and, consequently, if he had made a false statement in that particular, it would be no answer to say that the habits were not such as to impair his health, because insurers have a right to protect themselves by guarding against the risk of pernicious habits. (May on Ins. § 290.) But it seems to us an inquiry in regard to previous habits of drinking intoxicating liquors is not material unless they existed to such an extent as to affect the health or physical condition of the applicant, and thereby render him an unsatisfactory subject for life insurance."—*Boulting vs. New York Life Ins. Co. (Iowa)*, 166 N.W. 278.

Military Medicine.

Abdominal Wounds in War.—Dr. Joseph Rilus Eastman, writing in the *Journal of the Indiana State Medical Association* for November, 1917, classifies gunshot injuries of the abdomen as follows: (1) Slight superficial wounds: (a) Contusion; (b) Tangential gunshot of skin and fat; (c) Injury of musculature of abdomen, flank, back, and buttocks; (d) Injury of the peritoneum without penetration of abdomen. (2) Deep and serious wounds: (a) Extraperitoneal injury of hollow viscera, rectum, bladder, and colon; (b) Extraperitoneal injury of parenchymatous organs, for example the kidney; (c) Intraperitoneal injury of hollow viscera by missile; (d) Intraperitoneal injury of parenchymatous organs by missile; (e) Intraperitoneal injury of blood vessels; (f) Complicated intraperitoneal injuries, for example, simultaneous wounding of hollow viscera, parenchymatous organs and vessels; (g) Rare injuries, for example, those in which an intraperitoneal hollow viscera or parenchymatous organ is wounded by the impact of a missile against the peritoneum without penetration of the latter; (h) Injuries of intraperitoneal viscera as the result of the explosive force of missiles striking the pelvis or chest or of blunt objects striking the abdomen, for example, rupture of the intestine from a high velocity bullet traversing the pelvis without entering the peritoneal cavity, or rupture of a gut filled with gas or fluid as the result of a blow on the abdomen; (i) Wounds of the abdominal viscera complicated with wounds of the chest.

Hemorrhage in penetrating, nonperforating abdominal wounds may be due to: (1) Injury of the vessels of the omentum or mesentery; (2) Injury of the vessels of the folds of the peritoneum; (3) Injury of the liver, spleen, pancreas, or kidney; (4) Incomplete nonperforating injury of the stomach or intestine; (5) Various combinations of these injuries.

The general symptoms and signs of abdominal wounds with perforation are: (1) Site of aperture of entrance, presumptive sign if in anterior abdominal wall; (2) Pain-gripping or colicky about the umbilicus, later radiating to chest and groins; (3) Vomiting; if blood is vomited, stomach is probably perforated; (4) Hiccoughing; (5) Costal breathing; (6) Syndrome of shock, may also be due to hemorrhage without perforation; (7) Tympany; marked over upper abdomen when the patient is in the dorsal recumbent position and most marked over left hypochondrium when the patient lies upon the right side; (8) Board-like rigidity of abdominal muscles, reflex; (9) Abdominal tenderness; (10) Emphysema of the cellular tissue of the abdominal wall, occurring after wounds of the colon from *Bacillus coli* infection; (11) Elevation of temperature and other phenomena of perforation peritonitis.

There are three signs which, as stated by La Garde, may be regarded as positive evidence of intestinal perforation: (1) Escape of intestinal gas, feces, or intestinal worms from the wound of entrance or exit; (2) Protrusion of perforated gut at the wound; (3) Passing of the missile or passing of blood by the anus, red blood indicating

perforations of the colon or rectum, dark, bloody stools suggesting lesion of the small intestine.

The treatment of wounds involving the abdominal coverings is that of superficial wounds elsewhere. In penetrating and perforating wounds the diagnosis should be established and celiotomy done within the first five hours, if conditions are favorable for a skillful and aseptic operation.

Gunshot wounds of the *stomach* are of frequent incidence. Little value attaches to the symptom of hematemesis, as it is rarely present. Wounds of the anterior wall are, as a rule, easily found and readily closed. The wound on the posterior wall is not always easy to find nor is it easy to close by suture. When such a wound cannot be brought into view for closure by suture, drainage without suture is safer than blind and awkward attempts to repair the wound, but an experienced surgeon will not often be driven to forego the suture of any stomach wound.

The *small intestine* is of all hollow viscera the most frequently perforated. There may be wounds of entrance and exit in each wounded coil of gut or a simple opening may be present, the result of a tangential shot. As a rule the openings are present in pairs, the wound of exit being the larger and accompanied by more marked extension of mucosa. One should operate if the patient is not in a hopeless condition and if a skillful aseptic operation is possible. To make sure that no injury is overlooked the entire intestine should be examined at the ligament of Treitz. Small round perforations are closed with a single purse-string suture of silk or linen. In larger ragged wounds of the gut a running suture is efficient in securing accurate closure of the serosa over the defect. In extensive tangential lacerations the application of the running Lembert suture should be preceded by closure of the wound with a simple running suture traversing the entire thickness of the gut wall. In wounds of the intestine at the mesenteric border care must be taken that the perforation in the muscular coat of the intestine itself is closed. With this in mind the edges of the wound of the mesentery should be separated to allow a good view of the opening into the intestine. After turning in the muscularis and mucosa of the gut at the site of perforation with Lembert sutures, the opening in the mesentery is closed with a simple running suture. Injuries causing complete division of the gut require circular suture anastomosis or invagination of the ends with lateral anastomosis. The latter is the safer and amounts eventually to circular suture since the gut at the site of lateral anastomosis straightens out and assumes a nearly normal conformation.

La Garde states that gunshot wounds of the *large intestine* covered by peritoneum, except those of the transverse colon, are never so fatal as those of the small intestine. The interesting point is that wounds of the small intestine higher up are more likely to be associated with injuries of other and vital organs than are wounds of the large gut. Extraperitoneal injuries of the rectum nearly always recover. On the other hand, all injuries of the rectum which establish communication with the peritoneal cavity are serious.

Owing to the small size of the organs wounds of the *kidneys* are not common. They are usually complicated by wounds of other important viscera. There is nearly always saturation of the fatty capsule and surrounding tissues with blood. Wounds of the kidney, are, as a rule, accompanied by injuries of the intestines. If there is no evidence of perforation of the gut, the kidney injury should be treated conservatively. If the renal vessels are divided or great destruction of the kidney has occurred, nephrectomy is required. As a rule, however, it may be stated that rifle bullet wounds of the kidney are best treated by rest and opium.

Wounds of the *bladder* rarely produce dangerous hemorrhage. The urine is normally not infectious, but if emptied into the peritoneal cavity causes more or less chemical irritation. Obviously extraperitoneal wounds of the bladder are less serious than those which involve the peritoneal cavity. Hemorrhage into the bladder suggests an extraperitoneal injury of the bladder. An empty bladder suggests intraperitoneal injury of the bladder with escape of urine into the peritoneal cavity. Intraperitoneal wounds demand abdominal operation if conditions are favorable. If not, a retention catheter should be introduced promptly. Extraperitoneal wounds are best treated by continuous catheterization or by perineal section.

A clear-cut wound of the *liver* is rare and lacerations are the rule. Hemorrhage is always present, the degree depending upon the size of the vessels involved. Fortunately, the liver tends to tear and give way between the large vessels. Near the hilus, however, the danger of injury to large vessels is great. Liver hemorrhage often subsides spontaneously. Blood pressure in the liver is low and the bleeding may be controlled nearly always by pressure with gauze pads. In wounds of the liver communicating with the chest, hemorrhage is into the chest cavity rather than into the abdomen, since intraabdominal pressure is greater than intrathoracic pressure. If there be extensive laceration of the diaphragm the liver tissue may be extended into the chest. Uncomplicated gunshot wounds of the liver require no surgical treatment unless there is serious hemorrhage, and this hemorrhage may be controlled in nearly all cases by gauze packing, which is left protruding at the abdominal wound. For liver suture a blunt needle and large-sized catgut are used. The ends of the catgut on each side of the wound should be passed through or around gauze strips of several thicknesses to prevent cutting out.

Injuries of the *spleen* are comparatively rare. Uncomplicated wounds of the spleen are rarely seen. It is believed that injuries of the spleen at some distance from the hilus often heal spontaneously. The blood pressure is low and hemorrhage may not be serious. Treatment consists in control of bleeding by gauze pack, suture with a blunt needle, or splenectomy.

Pancreas wounds are usually complicated. The hemorrhage is usually great and the prognosis is bad. The surgical indications are control of bleeding by suture or gauze pack with lumbar drainage.

The Petty Cardiac.—Lian refers to a form of cardiac disorder of toxi-infectious origin which occurs in young soldiers with the expression of effort dyspnea and palpitation and is functional throughout, as far as valvular lesions are concerned. These patients have been ranked among pseudocardiacs, but the author believes that petty cardiac is a more suitable term, regarding the probability that the myocardium is directly acted upon by some toxi-infectious principle. Of 350 cardiacs examined 70, or 20 per cent., were placed under this head. As a rule there is a history of some cardiac disturbance before the war expressed as effort dyspnea, palpitation, and precordial distress. The degree varies extremely. During the war the infantry soldier when on the march may suffer a crisis of dyspnea which forces him to step out of the ranks. As a rule, when he recovers, he is able to catch up with the command. But his troubles become worse. There is a general tremor, palpitation, throbbing of the carotids, confusion, vertigo; and, if he persists, syncope. If one of these soldiers is examined recumbent, as a rule, nothing whatever is found, although upon standing the pulse beat is usually accelerated. There is, however, a tachycardiac type and an arrhythmic type. Most of the cases are seen in the chronic stage, but there is an acute period in which fever is present. In two-thirds of all cases the condition to which the cardiac lesion is secondary is acute articular rheumatism. The other third is due to other infections—typhoid, scarlatina, grippe, pneumonia, etc., etc. In other words, these petty cardiacs should be readily isolated by the history of an infection. In the rheumatic as well as septic cases there is a sharp distinction between simple myocarditis and endocarditis; for a subject with the latter case can hardly be termed a petty cardiac even if the valvular lesion is latent. In both endo- and peri-carditis the myocardium usually participates. The existence of simple myocarditis in these cases in troops has not yet been confirmed by autopsy, and the intimate nature of the process can only be surmised. The author believes that the so-called sinus region is chiefly involved. His views are not solitary in regard to the cases in question for several experts have described a "toxi-infectious palpitation"—among others Mackenzie and Vaquer. That is to say, palpitations are often seen in the wake of some infection. When a soldier reports with effort dyspnea and palpitation he should always be interrogated as to possible past infection. The latter need not be recent, but, as a rule, the first history of either symptom should extend back to an attack of acute rheumatism or other accident of the sort. Another point brought out in the history should be hardships before the aggravated appearance of the symptoms. This chain of events—infection, slight cardiac disorders, forced march, etc., and aggravation of symptoms should serve to isolate these cases from a number of other types of affected heart—the false cardiac included—not only those of mild character, but others dependent upon organic disease. Of other kinds of heart without valvular lesion to be borne in mind in diagnosis are hyperthyroid heart, simple dilatation and hypertrophy from functional abuse, the irritable soldiers' heart of the English

and Americans, the palpitations of tuberculosis, the reflex heart, etc. Of 350 cases studied by the author the chief categories were as follows: toxic infectious myocarditis, 70; so-called constitutional inadequacy of the circulation, 46; "war heart" (corresponding to soldier's heart), 43; valvular lesions, 35; simple hypertension, 32; disorders secondary to affections of the lungs, stomach, nervous system, etc., 59.—*La Presse Medicale*, January 10, 1918.

The Stethoscope an Aid in the Early Diagnosis of Gas Gangrene.—Capt. B. C. Maybury, R.A.M.C., writes in the *Journal of the Royal Army Medical Corps*, January, 1918, as follows concerning the stethoscope as an aid in the early diagnosis of gas gangrene. Many wounds exhibit a varying degree of swelling of the surrounding parts within twenty-four hours of their infliction. In a certain proportion of these cases, especially if the wounds are not drained, and the swelling increases and the part becomes infected with gaseous cellulitis, which is recognized clinically by well-known signs, e.g. resonant muscle, characteristic odor, etc. In the remainder gaseous cellulitis does not develop and the swelling gradually subsides under ordinary treatment. Crepitations can be detected by auscultation with a stethoscope of the portion of the limb infected with gaseous cellulitis. While this sign is present in a well-established case with "dummy muscles," its importance lies in the fact that it is present in a number of cases before the muscle becomes resonant to percussion, and it is therefore useful in distinguishing between the first group of cases mentioned above and the second. The sign is produced by placing the stethoscope on the swollen part and then alternately increasing and decreasing the amount of pressure applied to the chest-piece; this produces the necessary movement of the underlying muscle. Another method is to press the swollen part in several places with the finger, while the chest-piece is firmly placed on the center of the swollen area. The crepitations thus produced vary in intensity and number. In the early cases they resemble those heard in the lungs affected with chronic tubercle and may be few in number; in the later cases they are more numerous. In cases where subcutaneous gas is present they are much louder and are similar to those heard in ordinary subcutaneous surgical emphysema. The crepitations may disappear temporarily from a given area, if that area has been manipulated for a short time. Care should be taken to avoid mistaking the sounds produced by gas from those due to the pressure of blood clot and from those due to friction between the skin or hair and the stethoscope. The detection of these audible crepitations may be of use in two ways. 1. In cases in which they are present the wound should be more freely opened up than otherwise would be done, and if necessary secondary incisions with free transverse division of the deep fascia should be made into the muscle over which the crepitations have been heard. 2. During active operations when owing to the large number of cases admitted to the clearing stations it is impossible to drain all wounds involving muscular tissue. Cases in which crepi-

tations are present should have preference as regards operation over those in which they are absent.

Experiences in a Base Hospital.—Dr. Thomas McCrae read a paper on November 3, 1917, before the Johns Hopkins Medical Society, which was published in the *Johns Hopkins Hospital Bulletin*, March, 1918, dealing with some of his experiences at an active general base hospital in England of 2,080 beds, with a number of associated convalescent hospitals, so that the service was constantly moving. Dr. McCrae said in part that among the diseases peculiar to war, trench fever may be first mentioned. This is absolutely new so far as he could judge. The vast majority of the cases come from the trenches, but a certain number have arisen back of the trenches. Statements are made that the disease has originated in hospitals in Great Britain among nurses and orderlies waiting on patients with the disease. He was told that one case occurred in a nurse in the hospital where he was. He was able to prove that this was not so, and he could not find anyone who had definitely seen such a case. The patients have an onset much like any other acute febrile disease. They feel badly for a day or two, have a good deal of headache, malaria, chills, fever, and loss of appetite. The fever begins comparatively early and is not necessarily high. When these symptoms develop at the front, the men are sent down at once and McCrae saw some of them in about three or four days after the onset. In general, there is nothing particular in the examination, except one striking thing. They complain of pain, which is generally described as being in the shins. The fever is variable; it lasts sometimes five, six, or seven days, sometimes only three or four, and then drops and the temperature runs along for some days at normal. After this interval of from five to seven days there is a sudden elevation in temperature, the fever going up to 102°-104°. This persists for 24 hours and then drops to normal. There is another apyretic period for five to seven days, and then another paroxysm, the temperature again dropping to normal. That may go on for seven or eight attacks. The majority of the patients had two or three; after that the temperature was normal and there was no return of fever. With this elevation of temperature, there is apparently no increase in leucocytes. The pulse always goes up a little and the patient looks very ill. The point of particular interest is the condition of the legs called "painful shin." In the majority of cases the shin is very tender. In some cases when one goes near the bed the man implores you not to touch it, a condition the speaker had only observed otherwise in very severe cases of rheumatic fever. If a more careful examination be made tenderness behind the knees will often be found. Indeed a good many of the patients had as much tenderness on pressure behind the knees as in the shins. After the period of fever is over there is nothing left but this excruciating pain, which is usually worse at night, and it is very common to find these men sleeping during the day. Naturally, in such a condition symptomatic therapy is of importance, but it was not very successful. Locally, the application of a solution of Epsom salts gave

more relief than anything else. McCrac was interested in trying the effect of sunlight. It acted like magic in some cases, but unfortunately they were the exceptions. Some of the patients were not affected at all. The views as to the etiology are conflicting and not one has been confirmed. A good deal of evidence points to the fact that the disease is carried by lice.

Army Health Continues Good.—An announcement made by the War Department, on April 4, states that the health of the army in the United States continues good, although in many of the Northern camps the non-effective and death rates increased slightly over the preceding week. The total number of deaths reported was 237, of which 90 were among the regulars, 29 in the National Guard, and 118 in the National Army.

American Red Cross Meets Emergency.—According to a cablegram from Paris, the American Red Cross has performed another feat by preparing and shipping to a town behind the French front a tent hospital of 500 beds, within twelve hours after receiving a request from the French Government. The hospital was needed to care for patients suffering from fractured limbs who were being removed from a hospital in eastern France that was being menaced by German air raids. The equipment supplied by the Red Cross consisted of 25 tents 20 by 60 feet, each containing 20 beds. The Red Cross is making arrangements to send 50,000 Parisian children to a provincial center where they will be cared for during the summer.

Mineola Fair Grounds for Hospital.—After a conference between the Queens-Nassau Agricultural Society and a representative of the War Department, announcement is made that the fair grounds at Mineola, L. I., will be turned over to the Government for a convalescent hospital. The fair grounds comprise sixty-three acres and when the present buildings are remodeled will accommodate 10,000 patients. At present convalescent soldiers will be sent from the army cantonments but later those from over the seas will probably be placed there.

Urge Shorter Training Course for Nurses.—Dr. Charles B. Grimshaw, the superintendent of the Roosevelt Hospital, has sent a letter to the president of the New York Academy of Medicine showing that there will be a shortage of nurses for several years to come. He urges the New York Academy of Medicine to recommend that hospital units be used as schools, and that the number of nurses in training schools be increased to the full housing capacity. He also recommends a reduction of the training course from three to two years, stating that the latter period has given satisfactory results in Roosevelt Hospital. Other authorities, familiar with the work of nurses' training schools are much opposed to shortening the course.

Army Medical Corps Examinations.—The Surgeon-General of the Army announces that preliminary examinations for the appointment of first lieutenants in the Medical Corps of the United States Army are being held at numerous points throughout the United States, on the first Monday

of each month. There are at present 650 vacancies in the Medical Corps of the Army. The essential requirements to securing an invitation to report for examination are that the applicant shall be a graduate of a medical school legally authorized to confer the degree of Doctor of Medicine, of good moral character, and have at least one year's post-graduate hospital internship. A first lieutenant receives \$2,000 a year and during the period of the war will be promoted to captain within a year, subject to examination and receive a 10 per cent. increase in salary. Further information may be had by communicating with the Surgeon-General United States Army, Washington, D. C.

Hospitals Assigned to American Fund for French Wounded.—The New York Office of the American Fund for French Wounded has received a cablegram from its headquarters in Paris stating that the American Red Cross has assigned to the American Fund the care of several base hospitals back of the firing line to be used for the American and French wounded.

Government Takes Over Hoboken School.—The Medical Corps of the United States Army has made arrangements to use Public School No. 6, Hoboken, N. J., as a military base hospital. The school building has a capacity for 500 beds.

New Reeducational Clinic.—Through the beneficence of an anonymous donor New York is to have a new clinic for the functional reeducation of maimed military men and civilians. The new institution will occupy the plant formerly used by the New York Infirmary for Women and Children at Stuyvesant Square and Fifteenth Street. During the war it will concern itself largely with military work, but it is the intention of its founders to make it a permanent organization for the benefit of the industrial maimed of peace times. The institution is to be known as the New York Clinic for Functional Reeducation of Disabled Soldiers, Sailors, and Civilians. Dr. W. Gilman Thompson is president of the organization.

Medical Reserve Corps Needs More Men.—An earnest call is made for more physicians in the Medical Reserve Corps following an increase in the number of assignments to active duty. The Surgeon-General reported on March 22 that there was a total of 18,138 officers in the Medical Reserve Corps and of this number 15,174 are now on active duty.

Dr. Anna Von Sholly of New York City, who is serving with the Women's Overseas Hospital at Paris, has, according to a recent cablegram, been caught in the zone of fighting where she went to prepare a new hospital for occupation. At the time the message was sent she had been cut off from her headquarters in Paris for several days.

Antivivisectionist Propaganda Denounced as Treasonable.—Representative Charles F. Reavis of Nebraska recently denounced before the House of Representatives a circular issued by the National Antivivisection Federation which asserted that inoculation of American soldiers was causing thousands of deaths in army cantonments. He has sent the circular to the Department of Justice with the recommendation that action be taken against the members of the Federation.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, April 13, 1918.

A PHILOSOPHY OF MEDICINE.

IT has been said that a branch of knowledge cannot stop at a scientific rationalization, but must go on to a philosophy, which will not only determine its intrinsic but its extrinsic relationships. One man who thus expressed himself was Herbert Spencer, and it should indeed require a Spencerian mind to write a philosophy of medicine, for it is to be feared that the profession is too much occupied with asserting its own rights and seeking for cohesiveness to consider in a dispassionate manner the relationships of medicine to the general scheme of creation. It is at once a source of comfort and of despair to bear in mind that Spencer, had he attempted to write a philosophy of medicine in his best years, would have failed miserably because the sciences upon which medicine is founded have been substantially transformed since that period. It is only too evident that in a philosophy of medicine the general advance of science—since it cannot be foreseen—must be largely left out of consideration.

At present we can only touch on certain detached aspects of medicine which are seldom borne in mind by physicians but are very obvious to the public and which would certainly require incorporation into a philosophy of medicine. The medical man is tacitly assumed to understand all that concerns the body and mind. In his student years he spends much time on anatomy and physiology and no one would think of denying that he must be thoroughly familiar not only with the normal man but also with those slight borderline deviations from the normal which fall short of actual disease. He is called upon to treat and judge insanity, and hence has been the final authority on the mind. But these assumptions are largely gratuitous, for there are chapters and chapters on the body and mind of which the medical practitioner is, to say the least, very poorly informed. His is in fact but one of a score of professions through which services are rendered to the body and mind or which require great familiarity with the organism in some particular aspect. We may enumerate here high as well as humble callings. Many divines and teachers have been well qualified to improve their op-

portunities of unlimited contact with the human mind and its influence on the body. Doubtless the medical man could learn much from the Jesuit fathers and the writings of Emerson, as he could also from the great pedagogues of the past and present. The athletic trainer, physical director, boxing instructor, masseur, barber, undertaker, can all teach him something about the body.

A barber on a busy city corner may see and handle more scalps in a month than a great expert in scalp affections sees in a lifetime. Is there no way by which these opportunities for observation can be made to yield information for the common weal? The fact is well known that constant familiarity with a given subject by a layman or undergraduate gives him a technical eminence for the nonce which is superior to the consultant in medicine. The late Dr. Oren Pomeroy used to tell with glee about a student who became so obsessed with the ophthalmoscope that he devoted most of his time to the study of eyegrounds and came to be indispensable in all consultation work in a well-known eye hospital. His labors in this field having been interrupted he soon fell off in his ability to see what others could not. There are stories about dissecting-room roustabouts who became superb anatomists because they had no other outlet for their activities. But we need no muster of facts to uphold the existence of this kind of making good, for it is only common sense and daily experience.

We naturally think of the medical man as the chief contributor to the general weal in the direction of public health activities. Many things done formerly in the name of mere utility are done to-day in the name of hygiene. Cities once asked only for plenty of potable water and the problem was purely one of engineering. To-day the water must also be sterile. The same change in viewpoint is present universally. Hence thousands of men to-day—employees of city, State, or central government—earn their livelihood by efforts to improve the public's physical well-being. From an entirely different angle, and largely in the interest of economical utilization of countless forms of plants and herbs—with various animal and mineral products—thousands of individuals are occupied to-day in the drug industry. The exploitation of these industries by patent medicine advertisers should not blind us to the fact that the utilization of these substances for the public weal is praiseworthy on several grounds. Not only does it represent a vast amount of salvage, but it enables a very large fraction of the general public to add legitimately to their incomes.

THE IMPORTANCE OF EXERCISE IN EARLY LIFE.

THAT exercise is healthful, indeed is essential to good health in early life, is a matter which admits of no argument. Yet it is obvious that such exer-

cise should be taken with discretion, as too much exercise in youth is as harmful as too little. It is largely a question of the personal equation, seeing that a child inherits certain mental and physical characteristics which may be developed or retarded by judicious training. The mental powers should not be unduly exercised at the expense of the physical, nor should the physical powers be strained to the detriment of the mental. The endeavor should be to strike the happy medium and to encourage the faculties of the mind and body both to attain to full fruition.

As a rule, teachers are apt to forget or to be indifferent to the truth that "all work and no play makes Jack a dull boy"; or, if it does not make him a dull boy, will render him a nervous, unhealthy specimen of youth. The boy or girl who does not possess a healthy body is incapable of assimilating more than a certain amount of knowledge, or the effort in gaining and retaining such mental pabulum will result in bringing about mental indigestion, injuring health and shortening life. As Dr. Edred M. Corner has pointed out in a paper published in the *Medical Press* of February 20, 1918, parents must be educated to understand that the highest and most acceptable endowment which they can bestow upon their children is good health, and later a sound education is to be grafted on it by forethought and foresight on the part of both parents and teachers.

According to Corner, physical education in the wider sense of team work, that is team work of school games, is perhaps the most valuable part of school life. Further, it may be emphasized that physical education requires as much forethought, method and application as mental. A master, a new creation, skilled and educated, must appear and take charge of it; not merely an exponent of the art of the game, but one familiar with the science of physical culture, which means that games should be supervised in a scientific manner in order that one part of the body or one set of muscles should not be exercised at the expense of the other part or set of muscles. Physical training, as far as possible, should be of a uniform nature, and yet should not be purely gymnastic, but should be taken in the form of games, which add a keen zest to the flavor and provide a healthy stimulus to the mind. Monotony of play, as of work, is to be avoided. Variety is the spice of life, and change of work and change of play are as important as variety of diet. Natural tastes and instinctive aversions must be heeded, at any rate to a considerable extent.

Corner places his finger upon the weak spot in our system of education, and his strictures thereon are as applicable to education in this country as in Great Britain. The physical education of girls is referred to, yet they need bodily education no less than their brothers. The time has certainly gone when it was considered almost indecent for a girl to indulge in physical exercises or exertion. Not

many years ago the ideal girl, regarded from the physical standpoint, was distinctly delicate looking, not to say anemic, and it was deemed vulgar if she bore upon her face the hue of health or the effects of the sun and wind. Now it is esteemed a mark of superiority if a girl is somewhat athletic, has a complexion glowing with health, walks with springing step, and is altogether a robust specimen of girlhood. Perfection of body, vigor of frame and constitution can only be reached by taking daily and appropriate exercise. This not only promotes muscular development but a vigorous nervous system and brain capacity, and aids in curbing that expenditure of nervous energy which is so frequent in girls. Physical exercise provides a healthy outlet for nervous repression.

Healthy children, and especially in these times, are the greatest asset of a nation. Healthy children will not be born unless their mothers are vigorous and healthy; and after all what will it profit a woman to cram her head with knowledge if, in the process, she becomes neurotic and incapable of bearing lusty offspring. If a girl wishes to go in for the higher education, her parents at least should insist that, ere she thus strains her mental and physical powers, she prepare her body by outdoor exercise to withstand this onslaught. It must be borne in mind that mental powers in women are developed at a high physiological cost, and that if she be not hardened she will suffer very serious depreciation of her nervous and bodily system. While physical culture is more urgently needed by girls than by boys, it is required by both sexes in their youth. There is room for sweeping reforms in this direction.

THE PROGNOSIS OF ACUTE PULMONARY EDEMA.

A PAROXYSM of acute pulmonary edema must always be considered serious, and therefore the prognosis must be guarded. The attack may prove fatal or, if recovered from, there is always the chance of a recurrence, and only too frequently it is a symptom of a usually incurable organic affection which will sooner or later end in death. The immediate gravity of an attack of edema of the lungs is naturally derived from an examination of the patient and an analysis of the symptoms offered, but of these there are two which should above all govern the prognosis, namely, the temperature and the expectoration.

The temperature does not usually go up in this process, and often it is subnormal, and the rare instances in which there was fever have almost all ended in death, regardless of the energetic therapeutic measures resorted to. From the viewpoint of the prognosis, the expectoration is of greater import than the temperature and better proven by a larger number of clinical observations. When the expectoration appears at the very onset of the process, and in quantity is in relationship to the râles and other sounds heard on auscultation, one may have reason to hope for the patient's recovery.

But when the expectoration decreases or ceases without any evidence of a diminution of the stethoscopic signs, the situation is eminently serious, for the reason that a bronchoplegia, with or without a paresis of the diaphragm, is in play. The serous exudate no longer being eliminated invades the entire respiratory tree and the patient dies from progressive asphyxia. However, one should not assume that all patients who expectorate freely will survive the paroxysm. There are, unfortunately, instances in which the violence of the attack is such that the patient dies in spite of abundant expectoration which should free the inundated pulmonary parenchyma, and regardless of a copious abstraction of blood which is the only rational treatment of the condition. On the other hand, an energetic and early interference will often save patients who do not expectorate, even when the condition is most alarming.

As to the etiological circumstances which govern the degree of gravity of the paroxysm, it is rather a delicate matter to pass upon, but we believe that it is logical to admit that the degree of renal insufficiency is largely responsible in this respect. The severity of the prognosis of acute pulmonary edema will be greatly lessened, the earlier a correct diagnosis is made, and hence the earlier is a resort to energetic treatment. In the majority of cases a copious abstraction of blood will carry the patient through. A patient who has recovered from an attack of acute edema of the lungs is always liable to develop another paroxysm of greater severity within a few weeks or months, and this fact must ever be recalled when making the prognosis. Finally, the etiological diagnosis shows the evident gravity of this pulmonary process, which is very often symptomatic of serious lesions, such as aortitis or interstitial nephritis.

RESPONSIBILITY IN THE INEBRIATE.

THERE is still too much difference of opinion between what constitutes legal responsibility for crime and medical responsibility of action. While it may be difficult to divest the law of its conception of criminal responsibility from long-established precedent, it is unfortunate that not even the medical profession is in accord on all phases of this question. It would be desirable whenever the question of responsibility arose, whether in insanity or in inebriety, that everyone should agree on irresponsibility, once it is established that there is a change in the physical or mental constitution of the individual in question. While legally a man is responsible who knows the nature of his act and that it is wrong, yet it seems obvious that every action of an individual or of the will, so called, is always influenced by his physical or mental condition. In medicine, unlike in law, the free will has no place in intelligent discussion. If it is once established that the mind or even the body of an individual is diseased or disturbed then it must be conceded that all his ac-

tions are under the baneful influence of these conditions. The question of degree of disease or disturbance and therefore the degree of influence and responsibility is then too essential for consideration. The law gives even less consideration in the matter of responsibility to the alcoholic than to the insane. He is held to greater responsibility because he is said to have had a choice in his drunkenness. He is only relieved from responsibility if the crime required for its commission deliberate intent, deliberate premeditation, and if he was in such a state from intoxication as to be incapable of deliberate premeditation. But in keeping with the more progressive notions on inebriety, no one can truly be said to be an alcoholic from choice. The pathological inebriate can no more prevent his excessive indulgence than can the drug addict. They are both in the same class in every respect. Moreover, the alcohol habit is very often an hereditary condition of extreme sensibility to alcohol, and responsibility for the habit rests, if anywhere, with the ancestry. It is obvious that the alcohol habit can no more be put off at will than crime or disease. That this condition is far deeper than is the power of the will to put aside is shown by the fact that excessive indulgence is accompanied by organic degeneration as well as psychoses, which latter are often characteristic of alcohol poisoning. Crime, inebriety, insanity, and degeneracy go hand in hand so often that it seems that there would be little doubt of the somatic nature of this habit.

It is often said that the mental and degenerative conditions accompanying inebriety are caused by the willful indulgence in alcohol, but it seems more plausible to say that the over-indulgence in alcohol is born of the mental and physical degeneracy which is of hereditary origin. At any rate it is not logical to speak of moral considerations or considerations of free will in an inebriate. One who is so fully poisoned by alcohol cannot be credited with moral motives or amenability to moral suasion. Alcohol paralyzes both mind and body and limits their activities; it creates in its addicts an inability to adjust themselves to the ever-changing conditions of life. The studies of the physiological action of alcohol on the brain and nervous tissues in general can leave no doubt of the pathological conditions induced in the minds of the inebriates. Whenever the fact of the habitual poisonous use of alcohol by an individual is established the sufferer should be given institutional custodial care and not vindictive or correctional punishment, no matter how heinous the offense; the treatment must be the same as that of the insane.

THE SOCIAL SERVICE EXCHANGE.

IN a free democratic community organization there is bound to be a certain amount of overlapping of effort with the concomitant waste of energy and funds. It is true of every branch of life, in busi-

ness, science, and philanthropy. Efforts are being made constantly to eliminate duplication as far as possible, and in an endeavor to achieve this we frequently pool our interests.

There has been a considerable amount of this sort of waste in hospital and charitable work. The same person would frequently be treated for his ailment in several dispensaries and hospitals, or would get aid from several agencies not knowing of each other's contributions. To check the possibilities of such abuse various plans have been suggested and various agencies called into being. One of these is the Social Service Exchange. It is a clearing house for charitable work, not dissimilar to the financial clearing house. As the latter clears checks drawn upon the various member banks, so the former "clears" drafts upon the various philanthropic agencies of the city. Under the plan in operation the name of the person applying for relief in any of the agencies using the exchange is sent to the central office, where it is kept for future reference. There information bearing upon the client's vital interests is recorded on a special card. When, at some future date, the same client appears in another connection his name is again "cleared," and immediately the new organization is informed with regard to all the important facts concerning that client. This system enables the various agencies interested to get such information as is available without waste of time or duplication of effort. At the same time it protects the institutions against the practices of unscrupulous persons.

The hospitals and dispensaries are agencies which come very close to the interests of our population. The facts about ill health and disability are ascertained there. The information obtained by hospitals and dispensaries is very frequently indispensable in the proper disposition of the cases and in laying proper plans for families. It is, therefore, of greatest importance that the dispensaries and hospitals, like other philanthropic agencies, "clear" their cases in a regular and systematic way. This does not mean that the names of all charity patients in hospitals or dispensaries should be reported to the Social Service Exchange, but it does mean that all cases suffering from conditions which have an important economic or social bearing should be "cleared" in the exchange. In return for this important cooperation the hospitals and dispensaries can obtain from the Social Service Exchange information as to the financial status of the patient and whether he is entitled to free treatment. They can also get very quickly, and without special investigation, all the available information about the home condition of the patient. Likewise, they can very easily find out whether the patient is receiving support from some philanthropic organization, and save the time and effort of the social-service workers.

When the slogan of the day is elimination of waste and inefficiency, it is important that the hospitals and dispensaries make greater use of the free facilities offered by the Social Service Exchange than they have heretofore.

A NEW CALL TO SERVICE.

ON page 647 of this issue of the MEDICAL RECORD is a letter from Surgeon General Gorgas, to which we would call our readers' most serious attention. It is nothing less than a summons to the medical profession of the country to come to the aid of the Government in its undertaking to win this war. There seems to be an impression abroad that we have done well, that we have done our share, or more than our share, in giving some 12 per cent. of our members to the medical services of the army and navy. We have done well, or rather we have begun well, but now much more will be demanded of us, and we shall have to meet the demand. General Gorgas states that there are to-day something over 15,000 officers in the Medical Reserve, all of whom will be needed to care for the men now or soon to be in France. Up to the present there has been little in the way of war surgery for our officers "over there," but soon, perhaps before these lines are printed, there will be enough, and more than enough, of that sort of work for every man in the Medical Corps. In the meanwhile there will be several drafts this year, each of which will require a certain number of medical officers, and these medical officers will need training before they are ready to discharge their new duties properly. But this training takes time, and volunteers are therefore needed at once. There are still numbers of young, and even middle-aged, men who are free to offer themselves without injustice to those they leave behind, many, indeed, with no impediment whatever. It is of these that the sacrifice is first demanded. Sacrifice? No, privilege!

UTILIZATION OF EPILEPTICS IN THE WAR ZONE.

AGOSTINI in the *Giornale di Medicina Militare*, January 31, seriously discusses this subject. The likelihood of seizures at inopportune moments would ordinarily eliminate the epileptic from any sort of military service. Nevertheless "epilepsy is a very elastic term, comprising numerous conditions in which major crises do not occur, as well as states which, while attended with convulsions, belong not really under epilepsy but under psychasthenia. It is the subject who suffers only with the infrequent mild or abortive crisis or symptomatic paroxysm who could be utilized for military work. It is admitted that war has caused or awakened only a very small number of cases of true epilepsy. Many subjects of trifling epilepsy are interned in insane asylums and prisons and some of them have learned trades and become skilled workmen. Such men are also found in civil life, supporting themselves and but little inconvenienced by their infrequent, mild seizures. Of 142 alleged epileptics referred to the author's insane asylum, not over a third proved to be true epileptics. The same overwhelming proportion of false epileptics occurs in other statistics. Apparently the skilled artisans among these subjects are those most needed.

ENLIGHTENED CANADA.

THE Canadian government, wishing to reduce the war burdens so far as it could, and to encourage the widest dissemination of knowledge, some time ago

reduced the postage rate upon Canadian publications 50 per cent. during the continuance of the war. It has established no zone rate of postage by which the printed word is reduced to the same level as salt pork and tobacco, but sends any newspaper, magazine, or medical journal from its place of publication to any part of the British Empire—London, Shanghai, Bombay, or Jamaica—at the rate of one-quarter cent per pound. Publishers in the United States pay four times as much, or one cent per pound, on their publications to any part of the country, but on July 1, unless the burdensome law passed some time ago by Congress is repealed, this rate, already four times that in Canada, will be increased from 50 to 900 per cent., according to the distance from the place of publication at which the subscriber lives. This is an unjustifiable addition to the already grievous burdens of the war; these burdens are borne willingly and without complaining, for they are necessary to win the war, but the institution of the zone rate for second-class postal matter is a purely domestic tax, not advocated or needed as a war measure, but one that is simply oppressive. Canada reduces her postal rate 50 per cent., the United States increases hers 50 to 900 per cent.—but comparisons are odious, and sometimes humiliating. Some weeks ago we referred to this, and asked our subscribers to write to their representatives in Congress to repeal the law. It now is only about eleven weeks to the time when the law goes into effect, the law has not yet been repealed, and another letter may give just the necessary impetus to bring about its abrogation. Write this letter to your congressman, and write it now, before you forget; the next time you remember it it may be too late.

News of the Week.

Bills Providing for Insane.—Bills are pending in the Legislature of New York State providing for two new State hospitals for the insane in the metropolitan district. The Creedmore site is proposed for one of these. A site for the other has not yet been selected. The pending bills also ask for the enlargement of existing State hospitals in and near New York City; the completion of the State Hospital at Marcy, and the establishment of a psychopathic hospital in New York City. The measure also provides for a new State Board to handle the problem of the feeble-minded, and recommends a state-wide census, a uniform commitment law providing for defective delinquents, and the reclassification and redistribution of feeble-minded persons now confined in large numbers in reformatories and other institutions. The appropriation bill now before the Legislature provides for a total of about \$2,500,000 in authorizations and appropriations for the construction of new buildings.

Drug Addiction.—As a result of a study of the problems of drug addiction by the Public Health Committee of the New York Academy of Medicine and the New York Psychiatric Society, a set of recommendations has been prepared urging that the Federal Government abolish the manufacture of heroine altogether and control and regulate the sale and distribution of opium and its derivatives and of cocaine, from the time of its manufacture to the

time of its final distribution, and also that it take measures to prevent the importation of these drugs. It is recommended that the Federal Government do not at present extend its jurisdiction to the control of all habit-forming drugs, but that control of special drugs be taken up as occasion demands. A thorough study of drug addiction is recommended in reference to the age, sex, occupation, environment, mental and physical condition of victims, and as to how their habit was formed. Examination of a long series of addicts at Bellevue Hospital shows that about 4 per cent. formed the habit through the advice and prescriptions of physicians. It is further recommended that the State do not at present undertake the cure of a drug addiction, but that at the present time it do what it can to prevent the development of new cases and encourage provision of relief of present sufferers. For this purpose the use of psychopathic hospitals or pavilions is suggested, and that special provisions be made in general hospitals throughout the State to care, under proper control, for those who ask for a withdrawal treatment. Finally, pending Federal action, it is recommended that the State of New York enact some law which will control the matter of drug addiction, and the use of drugs by physicians, in a better, more efficient, and practical way than does the present law.

Bill to Remove Restrictions from Osteopaths.—A bill is now pending before the Legislature of the State of New York which would amend the Public Health Law by removing the limitations now placed upon the practice of osteopathy which prevents these practitioners from administering drugs or performing surgical operations. Health Commissioner Amster has requested the city's legal representative to express the Health Department's disapproval of this measure.

Investigation Shows No Glass in Food.—The New York City Health Department has analyzed more than 100 samples of bread, rolls, candy, and other foodstuffs said to contain glass. Only one sample contained a small piece of glass, and an examination of the whole stock of that kind of candy revealed no more glass. Fifty per cent. of the suspected samples contained only sand or grit, probably the result of slovenly manufacture. Of 19 samples of food sent by the Federal Food Board not one has been found to contain glass. The Department of Health warns the public "that unless this thing is checked by an appeal to reason there will be a wave of hysteria that may result in something worse."

Fire Destroys Morristown Hospital.—The historic Morristown Hospital, which was erected in 1770, and for many years served as a tavern, was recently destroyed by fire. All the patients were removed to safety. The loss is estimated at \$100,000.

Bill Removing Restrictions on Oleomargarine.—There is a bill before the Legislature of the State of New York which would remove the restrictions which now prohibit the use of oleomargarine and butter substitutes in institutions maintained wholly or in part by the public moneys. The Department of Health has expressed its approval of this measure, and points out that the obligation to use butter in public institutions places an undue

burden on the taxpayers by prohibiting the city authorities from purchasing a wholesome and nutritious substitute for butter. The Health Department believes it should rest with the officials in charge of institutions to determine whether or not it is advisable to supply the inmates of public institutions with butter or a wholesome, nutritious substitute.

Duty of Physicians With Respect to Abortions and Homicides.—The Chief Medical Examiner of New York City calls the attention of physicians to a duty often neglected in cases of abortion. He finds attending surgeons, gynecologists, and their staffs of internes, singularly unaware of their responsibility to the prosecuting authorities in regard to the preservation of the pathological material of such abortions, namely, the curettings, and in some cases the uterus removed by hysterectomy. Neglect to preserve such material renders the physician *particeps criminis* to any action which the district attorney of the county may deem necessary. The attention of physicians is also called to the frequent failure on the part of physicians to properly preserve and identify bullets removed by them at operation from the subjects of homicidal attacks.

Epidemic in Ford Plant.—The officials of the Ford Motor Company confirm the report that more than 200 men have been affected daily by a malady resembling grippé. It is estimated that about 2,000 employees have been ill thus far, within a period of ten days.

Vital Statistics of Great Britain Encouraging.—The Registrar General of Great Britain, in a recent report to the Royal Statistical Society shows that but for the war the number of children born in the United Kingdom from May, 1915, to June, 1918, should have been 3,500,000, while the number actually born will be about 2,950,000. In Germany the number born should have been 5,850,000, and will be only about 3,250,000; while in Hungary there should have been 2,600,000, and there will be only 1,100,000. In the United Kingdom this will be equivalent to the loss of over six months' normal births; in Germany to a loss of seventeen months' births; in Hungary to more than twenty-four months. This report discloses the fact that the rate of infant mortality in the United Kingdom during the war years has been lower than at any previous period of like duration. In last July the infant mortality rate in large towns was 10 per 1,000 births, while in German towns of like size it was 76. In August the English figure was 36, and the German was 108; in Halle it reached 145, and in Cologne 283. Deaths from alcoholism in the United Kingdom declined from 53 for each million persons living in 1914 to 29 in 1916. The surplus births over deaths in the United Kingdom during the war is very considerably greater than the total loss of lives of English, Welsh, Scotch, and Irish soldiers during the period of the war.

Dr. Stephen Smith has resigned as member of the State Board of Charities, an office which he has held continuously since 1881, with the exception of six years, from 1882-88, when he was a member of the State Commission in Lunacy. Dr. Smith was 95 years of age on February 19.

The Pawtucket Medical Association, at its annual meeting, in Providence, R. I., on March 21,

elected the following officers: *President*, Dr. A. H. Merdinyan; *Vice-President*, Dr. E. J. Mathewson; *Secretary*, Dr. C. H. Thibodeau; *Treasurer*, Dr. S. A. Hughes.

Examination for Position of Pathological Physiologist.—The United States Civil Service Commission announces an open competitive examination for pathological physiologists, for men only, to fill a vacancy in the Hygienic Laboratory, Public Health Service, Washington, D. C. The position carries a salary of \$3,000 a year, and future vacancies requiring similar qualifications will be filled from this examination. Applicants should apply for form 2118, and for further information to the Civil Service Commission, Washington, D. C.

Obituary Notes.—Dr. FRANK H. WHITE, a graduate of the New York University Medical School, in 1882, and chief examining physician of the Hackensack Draft Exemption Board, died of pneumonia at the Hackensack Hospital, on April 2, aged 55 years.

Dr. OSCAR AUGUST BAST of Brooklyn, N. Y., died of pneumonia at his home in that city on March 27, aged 35 years. He was a graduate of the Long Island College Hospital in 1895, and later studied at Weisbaden, Germany.

Dr. GEORGE SCRIBNER TEN EYCK, formerly of Syracuse, a retired physician, died in New York City on March 29, aged 37 years. He was a graduate of the Syracuse University Medical College in 1897.

Dr. CLARENCE LINDER HOWES, a graduate of the Long Island College Hospital, Brooklyn, in 1878, died from pneumonia at his home in Hanover, Mass., on March 7, aged 69 years.

Dr. OLAF SOHLBERG of St. Paul, Minn., a graduate of the Minnesota Hospital Medical College, in 1884, died suddenly on March 6, aged 61 years.

Dr. WILLIAM G. ENYON, a former president of the Bronx County Medical Society, died of pneumonia in the New York Hospital, on March 24, aged 64 years. He was a graduate of Bellevue Hospital Medical College in 1887, assistant visiting physician to the Red Cross Hospital, attending physician to the House of Refuge, and consulting physician at the Bronx Eye and Ear Hospital.

Dr. ALBERT H. TANNER, a graduate of Bellevue Hospital Medical College, in 1874, died suddenly at his home in Brooklyn, Conn., on March 22, aged 66 years.

Dr. GEORGE HOSLEY SHEDD died suddenly at his home in Conway, N. H., on March 21, aged 65 years. He was a graduate of Maine Medical School in 1879, and head of the Memorial Hospital at North Conway.

Dr. MILFORD B. SHIPP, a pioneer physician of Utah, and a graduate of Jefferson Medical College, died at his home in Salt Lake City on March 14, aged 82 years.

Dr. JOSEPH F. DOYLE of Hartford, Conn., a recent graduate of the Baltimore Medical School, died at a local hospital following a surgical operation, on March 18.

Dr. M. H. SUMMERS, a pioneer resident of Columbus Junction, Iowa, died in Cedar Rapids on March 11, aged 68 years.

Dr. FRED P. JONES of Goshen, N. H., a graduate of New York University Medical College in 1877, died recently at the age of 65 years.

Correspondence.

VOLUNTEERS NEEDED FOR THE MEDICAL RESERVE CORPS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I wish to call to the attention of the profession at large the urgent need of additional medical officers. As the war progresses, the need for additional officers becomes each day more and more apparent. Although the medical profession of the country has responded as has no other profession, future response must be greater and greater. The department has almost reached the limit of medical officers available for assignment.

I am, therefore, appealing to you to bring to the attention of the profession the necessity for additional volunteers. So far, the United States has been involved only in the preparatory phase of this war. We are now about to enter upon the active or the fighting phase, a phase which will make enormous demands upon the resources of the country. The conservation of these resources, especially that of man power, depends entirely upon an adequate medical service. The morning papers publish a statement that by the end of the year a million and a half of men will be in France. Fifteen thousand medical officers will be required for that army alone. There are to-day on active duty 15,174 officers of the Medical Reserve Corps.

Within the next two or three months the second draft will be made, to be followed by other drafts, each of which will require its proportionate number of medical officers. There are at this time on the available list of the Reserve Corps an insufficient number of officers to meet the demands of this draft.

I cannot emphasize too strongly the supreme demand for medical officers. Will you give the department your assistance in obtaining these officers? It is not now a question of a few hundred medical men volunteering for service, but it is a question of the mobilization of the profession. In the large centers of population and at other convenient points, as well as at all army camps and cantonments, boards of officers have been convened for the purpose of examining candidates for commission in the Medical Reserve Corps of the army. An applicant for the Reserve should apply to the board nearest his home.

The requirements for commission in the Medical Reserve Corps are that the applicant be a male citizen of the United States, a graduate of a reputable school of medicine authorized to confer the degree of M.D., between the ages of 22 and 55, and professionally, morally, and physically qualified for service.

With deep appreciation of any service you may be able to render the department, I am

W. C. GORGAS,
Surgeon General, U. S. Army.

POISONING BY ARSPHENAMINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In view of the reports in current medical literature of untoward results from the use of arspenamine and neoarsphenamine, I have to request

that you give publicity to the statement that it is requested that samples of any lots of these arsenicals which have shown undue toxicity be forwarded to the Hygienic Laboratory of the U. S. Public Health Service, Washington, D. C., for examination.

In sending these samples it should be ascertained that the lot number is the same as that of the ampoules used on patients. The samples sent should, if possible, be accompanied by a brief note stating the approximate body weight and age of the patient, the dose and dilution of the drug given, the symptoms and result; that is, whether fatal or not.

G. W. MCCOY, M.D.,

Director, Hygienic Laboratory, U. S. P. H. S.

OUR LONDON LETTER.

(From Our Own Correspondent.)

INVALIDS AND COMPULSORY RATIONS—TUBERCULOSIS AND THE ARMY—THE TESTING OF SALVARSAN—CONTINENTAL HEALTH RESORTS FOR BRITISH INVALIDS.

LONDON, March 21, 1918.

THE rationing scheme for London and the "Home Counties," as the contiguous counties of the metropolis are termed, has now been in full swing for a fortnight and a very real feeling of relief is being experienced by the population involved. Apprehensions that the restrictions would prove too drastic have been largely allayed, for numberless people have found that the rational allowances are in bulk as great as they had been in the habit of consuming; others have had little difficulty in bringing down their previous consumption to the new scale, and yet others, who had placed no voluntary restrictions upon their appetites are finding the benefit of forced asceticism. The Ministry of Food, upon whom the duty has devolved of drawing up the regulations for compulsory rationing, have met the difficulty with regard to invalids as liberally as they have met the demand of children and nursing mothers for milk. Extra milk is now allowed not only to meet the needs of these physiological cases, but in the pathological states of pneumonia, enteric fever, acute abdominal conditions, and the cachexia dependent upon nephritis, tuberculosis, enteritis, dysentery, diarrhea, and gastric and duodenal ulceration. In all diseases associated with malnutrition extra milk may be ordered as well as extra butter and margarine, and in diabetes and tuberculosis extra meat is allowed. Extra sugar is only to be sanctioned on medical order in cases where there is difficulty in the mastication and deglutition of solid foods, as in malignant disease of the pharyngo-esophageal tract, or in gunshot wounds of the throat or jaw. The Ministry of Food recognizes no pathological condition as requiring cream, which may not be ordered by medical men. The Ministry of Food have taken the opportunity afforded by making a public pronouncement on the relaxation of rationing regulations for invalids to combat the distrust expressed in certain quarters of the bread now in use, which, owing to the inclusion of a higher percentage of wheat stuffs, has a darker color than the bread made of so-called "refined" flour. The Ministry state definitely that there is no evidence that any state of health warrants the ordering for invalids of bread made from

"superior" flour, a view with which most medical dieticians are in absolute accord. The concessions to invalids have been recognized by the medical profession as wise and liberal, the value of taking expert advice being thus proved, for the Ministry of Food have acted upon the advice of the Committee of Reference of the Royal College of Physicians of London and the Royal College of Surgeons of England, acting in concert with the Central Medical War Committee.

The huge British army has on the whole been wonderfully free from tuberculosis; if compulsory medical service has not proved the frequent method of open-air cure which was prognosticated, equally the strain of military service has not proved the abundant cause of breakdown which the pessimist expected would occur. But undoubtedly, and in particular in the early days of the war when the recruiting medical boards were not so well selected and were far less experienced in their work, many cases of incipient phthisis were allowed to enlist, while other cases of supposed cure were passed as sound with the idea that the tendency to relapse would be counteracted by the open-air life and good rationing of the soldier. Sometimes, however, there was no excuse for the reception into the army of tuberculosis cases, and certificates from tuberculosis medical officers, attached to the public health departments of various localities, were ignored by medical boards, who preferred to rely on their own diagnosis. The particular difficulty arising in this situation, apart from the cruelty to the individual and the immediate expense to the country of enlisting a man who becomes at once a hospital patient, formerly was that the question of pension was complicated by the difficulty of deciding whether the breakdown had occurred *because* of military service, or *during* medical service and because of pathological conditions existent before enlistment. This situation gave room for a good deal of argument and contrary scientific opinions, but these can no longer arise, for it is now decided that the enlisted man is enlisted free of tubercle, and that his breakdown later is the result of military service. An enormous improvement in the quality of the diagnosis of the medical recruiting boards has made this sensible policy possible.

The merits and demerits of salvarsan are to receive very thorough scrutiny at the hands of a competent scientific committee of inquiry, having regard to the differences of opinion on many matters which have manifested themselves as various centers for the control of venereal diseases which have lately been placed at the disposal of the public. The committee of inquiry has been appointed by the Medical Research Committee, and is therefore likely to be particularly acceptable to the public, inasmuch as the Medical Research Committee, though a government bureau or sub-bureau, represent the scientific side of the great democratic measure, the National Insurance Act. A certain fraction of the large tribute levied on employers and employed to finance that Act, is regularly allocated to the support of the Medical Research Committee whose original functions were to conduct research for the right directing of medical practice under the Act. But when the war broke out, and the country as a whole was seen to be engaged actively in a colossal

struggle, the services of the Medical Research Committee were placed at the disposal of the government for any and all war purposes, and some of the very best work in scientific therapeutics has been published under the reign of the committee, the circumstances inquired into being connected in all sorts of ways with the conditions of soldiers and sailors fighting for their country. At an early stage of the war it was seen that in all the armies of all the countries the incidence of venereal disease would play a disastrous part if unchecked; and it was also seen that, while prophylaxis and prevention, exercised by disciplinary measures and moral persuasion and advice, might work wonders, a large number of infections which had occurred could be cured by prompt treatment. Gonorrhea, most chronic and indirectly most dangerous of the ills to which the young adult is liable, can be rapidly cured, almost aborted, by simple chemical and mechanical means, with the result that the soldier finds himself back in the ranks in a few weeks, a wiser and no less efficient man than he was before; all that is required is prompt treatment along recognized lines. Syphilis is seen not to be so simple a problem; it is more difficult of diagnosis, and the treatment is not so regulated by universal agreement as to the best routine. In particular the use of salvarsan has given rise to differences of opinion; some men of experience consider salvarsan to be actually dangerous; many held opposing views as to dosage and method of administration; and many, while granting the virtues of salvarsan, believe that other substances can replace it with advantages of various sorts. Into all these matters the committee appointed by the Medical Research Committee will now inquire, and it will be of enormous use to medical men to receive from them an authoritative statement upon doubtful points. The view of the committee will carry weight, for its members form a strong tribunal. The chairman is Surgeon General H. D. Rolleston, senior physician to St. George's Hospital, London, and now consulting physician to the Royal Navy; the other members are: Dr. F. W. Andrewes and Professor W. Bulloch respectively professors of pathology and of bacteriology in the University of London; Dr. H. H. Dale, the director of bio-chemistry and pharmacology to the Medical Research Committee; Lieutenant-Colonel L. W. Harrison, one of the best-known workers on venereal diseases in the Royal Army Medical Corps; and Dr. F. J. H. Coutts, one of the assistant medical officers of the Local Government Board. The committee has been appointed with the idea that they should propose specific investigations into existing methods of employing salvarsan, and they are empowered to seek at any point the assistance of surgeons and others who are in a position to offer practical advice or communicate firsthand experience. The wide scope thus offered should result in the committee being placed in possession of all the facts that have led to differences of opinion as to the value of salvarsan, from which full comprehension of the situation authoritative suggestions should emerge.

Where a high altitude is needed—*i.e.* any altitude above 4000 feet—for the effective treatment of the British invalid it is obvious that recourse must be had to foreign lands. But it is universally borne in upon British medical men that the factor of altitude

and that of absolute humidity are the only ones that need trouble the physician when recommending his patient to try a sojourn in a home health resort. The variety offered in every circumstance of environment by the bracing north of Scotland, the bleak eastern coast, the high central plateau, and the subtropical softness of Cornwall and Devonshire meets the needs of almost all sick persons, and the number of patients whose life, or whose permanent cure, depends upon a continual sojourn is small indeed. British medical men have now been urged to remember this, and to make their recommendations to foreign resorts as infrequent as possible, as all cross-Channel traffic has been reduced to the lowest limits.

2. Is Early Operation Indicated in Fractures of the Spine with Cord Symptoms?—Alfred S. Taylor points out that there is little unanimity among neurologists, clinicians or surgeons as to the desirability of early interference in cases of fracture of the spine with cord symptoms. The question must be considered in relation to the different types of fracture and the resulting lesions of the cord. With the exception of bullet wounds where there has been complete division of the cord, in which case operation is hopeless, there is no question as to the desirability of surgical interference in fractures by direct violence. In fractures by indirect violence or those in which the line of fracture runs from the spinal canal margin downward and forward to the anterior aspect of the spinal column and again in those rare cases where the line of fracture is reversed, the primary aim of treatment, operative or non-operative, must be to preserve and restore the function of the damaged cord. The lesions of the cord associated with fracture of the spine may be classified as immediate and remote. The former include: (1) Contusion, associated with punctuate hemorrhages of the cord substance at the level of injury, and not infrequently accompanied by gross hematomyelia. In these cases there is always a secondary edema and the loss of the cord function may be partial or complete. After a time there is more or less complete recovery of cord function. (2) Internal distortion of the cord with permanent and complete loss of cord function. (3) Complete division of the cord with separation of the divided ends, in which case loss of function is complete and permanent. The damage to the cord consists of several components: complete division of elements of the cord, which occurs at the time of injury and is permanent regardless of the kind of treatment; hemorrhage, which causes cord symptoms which may clear up with the absorption of the blood; and edema, with loss of cord function which will be restored only if the edema is absorbed before the resultant pressure has caused degeneration of the cord elements. In addition, displaced bone fragments which press upon the cord will cause myelitis with loss of function. Taylor refers to the experiments of Allen, of Philadelphia, upon the cords of dogs, who found that to obtain recovery it was necessary to split the dura and cord very promptly after the impact. Although this could not be done so promptly in human subjects, Taylor performed a laminectomy with splitting of the

dura and incision of the cord on three patients, all of whom died within forty-eight hours. He concludes, therefore, that it is undesirable to subject fractured spines, where the vertebral bodies are involved, to operation within the first week, for the following reasons: Because it is not possible to operate with sufficient promptness to get the good results obtained by Allen in his experiments; because of the dangerous handling necessarily incident to operation, and the increase of false motion likely to follow the removal of the arches and their ligaments; and because of the impracticability of fixation of the fractured spine by external apparatus. In debatable cases in which it seems chiefly a question of the time when an exploration should be done, if there is increasing loss of function caused by secondary edema immediate operation may be indicated; on the other hand, if there is improvement after a few days there is less urgency for interference. Finally Taylor reaches the conclusion that operation should be deferred until the vertebral bodies have become solid enough to stand handling, and only then if improvement should be slow and unsatisfactory or should cease too soon.

1. Causation of Eczema, Urticaria, and Angioneurotic Edema by Proteins Other Than Those Derived from Food: Study XVIII.—Chandler Walker found that eczema was frequently associated with bronchial asthma in persons who are sensitive to various food proteins, and was able to prove that in some cases urticaria was caused by food proteins. He presents instances in which eczema, urticaria, and angioneurotic edema were produced by proteins which are not foods and have not previously been recognized as possible causes of these conditions. He found that horse dandruff, pollen of timothy, and pollen of ragweed, all caused eczema; that horse dandruff and ragweed pollen caused urticaria; and that timothy pollen, ragweed pollen, and flax seed all caused angioneurotic edema. Out of twelve patients, all with one exception (who was suffering from hay fever) had bronchial asthma, which was due to the same cause. Walker concludes that the proteins of horse dandruff, ragweed and timothy pollens may cause eczema both from external exposure and internal injection in predisposed persons. As is the case with food proteins, eczematous patients tolerate very small doses of the offending protein and the eczema seems to improve; but a slight increase in the amount makes the eczema worse. The amount of protein that benefits eczema is too small to prevent asthma, and the amount of protein that benefits asthma makes the associated eczema worse. Therefore, desensitization for eczema, if such is possible, must be a very slow and cautious process. Since small subcutaneous injections of the proteins or horse dandruff and ragweed pollen caused urticaria, it would seem advisable, in determining the cause of this condition, to exclude all protein substances with which the patient may come in contact as well as the food proteins. The same reasoning would apply to cases of angioneurotic edema. During the desensitization of patients with proteins, the appearance of eczema, urticaria, or angioneurotic edema should lead one to suspect that the treatment was the cause of such symptoms.

3. An Experimental Investigation of Lipovaccines. An Additional Note, with a Note on Triple Dysentery Lipovaccine.—E. R. Whitmore and E. A. Fennel point out that lipovaccines can be made on a large scale by growing the bacteria in Kolle flasks; taking off the

growth with a vacuum scraper; freezing and drying in vacuo, and emulsifying in lanolin and oil by grinding in a ball mill, using glass bottles and steel balls. The oils can be sterilized by steam at 15 pounds for fifteen minutes; by heating to 90°C. for ten hours on a water bath, or by mixing with potassium iodide. They state that experiments are being conducted to ascertain whether or not this method of sterilization will affect the antigen power of the vaccine. Ultraviolet rays are also being tried in the sterilization of the oil; and tests are under way to determine whether the antigen substances are extracted from the bacteria in an oil-suspended vaccine by heating, as is the case in a vaccine suspended in saline. In administering the vaccine Whitmore and Fennell have found a needle, No. 21, B. and S. gauge, with a cannula three-fourths of an inch long entirely satisfactory. Although the danger of fat embolism appears to be slight, they issue a definite warning that the injection should be made subcutaneously and care taken to avoid getting the vaccine into a vein. These authors found that they could give men a dose of 3,000 million Shiga, 3,200 million "T," and 2,200 million Flexner type of the dysentery bacillus in oil without marked local or general reaction. They also found that agglutinins, precipitins and bacteriolysins were produced in the blood of vaccinated animals and men, and that there was some evidence of complement fixation.

5. The Emotive Response to Ordinary Stimulation, Real and Imaginary. A. D. Waller.
6. A Case of Partial Gunshot Division of the Musculo-Spiral Nerve with Secondary Suture. Charles A. Morton.
7. A Note on the After-Treatment of the Radical Mastoid Operation. M. Lyon-Mercado.

3. Clinical Observations on the Effects of Flavine in Wound Treatment.—William Pearson selected for treatment with flavine two types of cases; those in which infection and sepsis were active and not under control when treatment was instituted, and those in which infection and sepsis has been controlled and repair had already begun before flavine was employed. No observations were made as to the "prophylactic" value of flavine in the abortive treatment of sepsis, but Pearson observes that the chief supporters of flavine from a theoretical point of view do not advocate its use as a substitute for hypochlorite solution in such procedures as that recommended by Carrel. The results of Pearson's observations are in agreement with those of Pridaux, and his conclusions have been arrived at from clinical use and observation alone. These conclusions are: (1) In cases where infection and sepsis are active and uncontrolled the use of flavine following suitable operative measures has no beneficial effect on the subsequent progress of the cases in so far as the control of sepsis is concerned. Any slight differences observed were unfavorable. (2) In cases where sepsis has already been controlled and repair has begun flavine acts injuriously, chiefly by producing an unhealthy granulating surface. Pearson adds that while these conclusions do not prove that flavine may not possess powerful germicidal properties in certain experimental conditions, he believes that they show that its clinical use is not attended with good results, and since completing his observations he has abandoned entirely the use of flavine. He further observes that a definite though minor objection to the use of flavine is its staining propensities and the difficulty of removing it from bed-clothes, bandages and utensils. White gauze, as used for packs in dressings, possesses a very powerful affinity for flavine. If a roll of gauze is soaked in flavine solution, even for several hours, it will be found that the outer layers are stained an intense yellow, but the central part of the roll is almost, or quite colorless. Similar experiments carried out with a loose bundle of gauze swabs showed the same result and it is obvious that white gauze has a considerable "filtering" (and "fixing") power on flavine, and this must modify its

action when used on gauze packs in wounds. Pearson points out that the treatment recommended by the Bland-Sutton Institute of Pathology would yield admirable results whether any antiseptic were employed or not. He considers statements as to the possibility of operating near an area already infected (e.g. secondary amputations) without a recrudescence of sepsis, when put forward as a proof of the value of flavine treatment, as scarcely worth considering.

1. Suggestions for the Prevention of Post-Operative Thrombosis and Embolism.—Frederick McCann is of the opinion that, although other factors may be contributory, post-operative thrombosis is largely due to the technique employed by the surgeon and that the chief fault may be expressed in the one word "transfixion." He points out that it is the improvement in surgical technique, especially in the direction of combating sepsis, that has reduced the number of cases of post-operative thrombosis and embolism, and he believes that the number of fatalities can still further be reduced by neat, clean workmanship founded on sound anatomical knowledge. He refers to the dangers of transfixion and states that "never transfix a vascular area" should become a surgical axiom. By transfixion, vessels are liable to be punctured and bleed either externally or into the tissues; the transfixing ligature is tied to arrest the bleeding and the result may be that the ligature remains in the lumen of the vessel. Should this ligature not be aseptic or become infected, the natural process of clotting in the vessel may be arrested, the clot liquefying and becoming detached. It is the milder infections that are followed by troublesome complications. The surgeon must cultivate delicacy of touch so that ligatures and sutures may be nicely and accurately adjusted without undue constriction. Round bodied needles are to be preferred to pedicle needles and, indeed, the latter should no longer be employed. Transfixion of the broad ligaments, the omentum and the mesentery is frequently done; McCann believes it to be a dangerous proceeding in each of these situations. In gastric and intestinal operations it is important to avoid puncturing the vessels in the walls of the stomach and intestine. Many accidents could also be avoided by due care and respect for the structure of the abdominal wall. In summing up the situation McCann lays down the following recommendations: (a) Do not transfix or puncture blood vessels; (b) Do not tie or stitch too tightly and cut into blood vessels; (c) Obtain accurate hemostasis, leaving no blood clots.

January 14, 1918.

Weil's Disease.—C. Klieneberger offers a general survey of this affection. His conclusions are that the diagnosis of serious and fairly marked cases of the disease is an easy matter. The more or less latent cases may cause difficulty in making a correct diagnosis. The icterus, nephritis, and splenic tumefaction may be wanting in the latter. Concomitant acute affections may mask the clinical picture of Weil's disease. The prognosis, formerly regarded as benign, is at present considered as giving a mortality of 13 per cent. The elements of gravity are: an irregular pulse, tachycardia, hemorrhages, a serious cerebral state and massive al-

buninuria and especially hypothermia with tachycardia and cerebral manifestations. Treatment is purely symptomatic, quinine and salvarsan being without effect, likewise the serum of convalescents. Dietetic treatment is important. At the time when great loss of chlorides arises the use of normal salt solution will prevent great emaciation from taking place.

The Cleansing and Cure of Torpid Bone Lesions by Filling in with Pedunculated Flaps.—J. F. S. Esser advises the general use of pedunculated flaps receiving a good vascular supply in order to instill vitality into bone, even in cases of infection and partial necrosis. Esser bases his view on a case of cranial bullet wound, the external table having been injured and giving rise to the formation of a cicatrix which prevented vascularization of the traumatic focus. At length, wearied by repeated operating, Esser removed a large portion of the external table and covered the wound surface with a skin flap taken in the occipital region. Light gauze drainage. The resulting occipital wound healed by granulation. The writer also reports a lacerated wound of the arm in which the biceps was bare over a large area, a condition which later on would interfere with its functions on account of the resulting cicatrix. Therefore a large plastic operation with a pedunculated cutaneo-fat flap was undertaken in order to avoid the above complication. [These extensive skin and fat flap operations in bone injuries have been resorted to on a somewhat large scale by the French surgeons, with extremely good results in many cases.]

Münchener medizinische Wochenschrift.

January 15, 1918.

The Contagiousness of Congenital Syphilis.—Werther points out the contempt often shown by members of the profession in regard to contagion from syphilitic babies, in spite of the frequent presence of the spirochetæ in the superficial lesions. This tendency is still more reinforced by the writings of many authorities. Werther relates ten cases of contagion from newly born luetics. In most of them it was only by a very searching anamnesis that the true origin of the various extra-genital lesions resulting from this manner of contagion could be detected.

A Preliminary Communication on the Treatment of Gonorrhea in the Female with Intravenous Injections of Collargol.—H. Menzi has met with excellent results with this treatment. The injections are given every second day, progressively increasing the dose of collargol solution at 2 per cent. from 2 to 10 c.c. Urethral inflammation, both acute and chronic, was cured in all cases. Out of a total of 24 cases in which the cervix uteri was infected, only one was not cured by the treatment. Two instances of very chronic metritis were uninfluenced by the injections, while three cases of arthritis were quickly recovered from. Infantile gonorrheas were cured after two to twelve injections had been given. Several of the patients treated had been subjected to a long treatment without results until collargol injections were used.

A Pseudogrippal Infectious Disease.—A. Schittenhelm and H. Schlecht have observed an epidemic which might very well have been mistaken for influenza, but Pfeiffer's bacillus could never be demonstrated. The distribution of the affection appeared to be the result of the very marshy region in which it broke out. The writers are of the opinion that the epidemic should be classed under the head of the psittacoses and the dengue. It did not appear that lice had any part in the transmission of the disease. Six typical case histories of the affection are recorded.

Deutsche medizinische Wochenschrift.

January 17, 1918.

The Comparative Value of Radiotherapy and Myomectomy.—Uhlirz criticises Nagel's point of view (reviewed in the issue of November 17, 1917; in Medical Record, February 9, 1918), and although not doubting the good operative results obtained by the latter and other operators, he points out that theoretically a truly specific action can be attributed to the x-rays on the myomatous cell, as well as on ovarian tissue, both these

tissues possessing morphological and biological cells belonging properly to them. Therefore, these cells can be placed electively beside the other tissues of the body.

The Interpretation of the Weil-Felix Reaction in Typhus Fever.—Braun and Salomon refer to the divergence of views existing on this subject, some writers maintaining that the reaction is a certain proof of the infection (Weil-Felix), while others look upon it as a reaction of the organism against the pathogenic agent itself (Friedberger). The writers have compared the biological and bacterial properties of the Proteins X 19 with those of other protein organisms found in pus, human urine, and feces. They have been unable to distinguish any character belonging individually to the X 19, excepting, perhaps, a more rapid production of indol in twenty-four hours. The protein organism of typhus fever are not always identical with each other and they greatly vary in their agglutinogenous properties when inoculated in animals. Several types or races of the proteins can be made out. Braun and Salomon have noted that the serum of inoculated rabbits first reacts against the X 19, and only afterwards against the X 2. This serum heated at 56 deg. C. for one hour loses its agglutinating properties and these are not revived by the addition of normal serum. In conclusion, the writers believe that a reply to the question of interpretation cannot be made at the present time. Besides the two opposed interpretations, one will do well to consider the solution of the following proposition, namely, during the progress of typhus fever the proteins having the characters of the X 2 may transform to the X 19 type, from which arises the specific reaction of the organism against this microbic family.

La Presse Médicale.

February 14, 1918.

Causes of Errors in the Wassermann Reaction.—Leradde and Rubinstein state that paradoxal reactions should be attributable to defective technique. It is necessary to search for such before trying to incriminate the serum. Defects are to be found especially in absence of titration, in poor serum and in the condition of the globules, and at times in the glassware and water used. Frankly positive and negative reactions seldom lend themselves to confusion. It is the partial reactions which make up the great majority of the paradoxal finds and the interpretation is often very difficult. Parallel tests with heated sera (Wassermann) and non-heated sera (Hecht) afford the best conditions for clean results. But for Hecht's reaction to be decisive certain conditions are required which will be discussed by the writers in a subsequent paper. The present article deals solely with the Wassermann. The latter always seems a simple matter to the novice and only years of experience make one alive to the possibilities of error through the clinical reports which come back to him. In fact the serologist and practitioner are mutually dependent on each other. Six components enter into the reaction and each may be a source of error. The apparatus constitutes a seventh component. Each possibility of error must be foreseen and provided against. Again in addition to these individual possibilities others arise in connection with their association in the reaction. Here a quantitative factor enters. There is not a unit or constant in the entire mechanism.

Diminution of Normal Transparency in Tuberculous Apices.—Lebon sums up his radioscopic experience as follows: the uncertainty and doubt attendant upon the precocious diagnosis of tuberculosis of the lungs are not always alleviated by a minute radioscopic examination. It is very difficult to back up with auscultation and percussion the contrasts which at once become visible on the screen, when an opacity has been visible to all who have remained in the dark room long enough for the retina to become adapted. The small condensation in the apex projects a shadow which is the more visible in proportion as the parenchyma in general is sound and permeable to air. The radiograph shows the condition perfectly. For a number of reasons, however, the difficulty in making out a simple diminution of transparency in the apex is much more difficult and the same degree of uncertainty inheres as in auscultation and percussion. Further radioscopy fails to reveal all the

tuberculous apices and numerous lesions when minute and discrete escape all x-ray examination whatever although in such cases we can readily hear a diminished vesicular murmur. Hence stethoscopic evidences still take precedence.

Correspondenz-Blatt für Schweizer Aerzte.

January 19, 1918.

Etiology and Prophylaxis of Goitre.—Bernhard writes very briefly of this subject. The late Kocher, not long before his death, alluded to the fish "goitre" as studied in the U. S. A. with reference to recovery of the animals when flowing is substituted for stagnant water, which makes possible greater movement; also to the good effects of iodine when added to the water; also to his own observation that goitre tends to begin at the school age and finally to the good results of military service. A feature of prophylaxis is the presence of a "healthy" well near every schoolhouse. The water may also be purified by ultraviolet rays or addition of iodine or boiling. However, natural sunlight is the best disinfectant and combined with exercise in free air is also a prophylactic for the child. A survey of shade dwellers and sun dwellers on the slopes of mountain valleys shows marked differences in constitution, the former being more dumpy in build and phlegmatic, while the latter are slender, lean and lively. The author believes that the favorable influence of solar light in the prophylaxis of goitre has never yet been duly honored. As sometimes happens, the intuition of a gifted layman has proved to be superior to the scientific knowledge of his day, and many years ago Balzac saw in absence of sunlight and free air the cause of cretinism. Tourists and those who take cures in Switzerland almost never become goitrous and naturally they visit the country only in the summer or sunny months. The author admits that at present his views are only hypothetical, but hopes they will be corroborated by the studies of others.

Pyelitis Infantum.—Wieland concludes his article on this subject as follows: Pyelitis (and pyelocystitis) is a characteristic febrile disease of childhood as yet not widely known. While it may be due to a variety of microorganisms, the *B. coli* causes a special clinical variety—col'pyelitis. In childhood the infection is chiefly of the descending and hematogenous types and the sudden development of isolated pyelitis speaks for the hematogenous route. After the nursing period female children are principally affected. The condition is very often a metastasis from a focal infection in the rhinopharynx or throat. Constipation and urinary stagnation are not causal factors, but exposure must be reckoned with. To detect the presence of this affection it should be regarded as necessary to examine the urinary sediment in all febrile conditions in young children, the urine being preferably obtained in girls by the catheter. The presence of leucocytes in the hanging drop is good evidence, although bacteriological tests are of course necessary. The condition is eminently a recurring one and may account for cases in the adult woman, especially in pregnancy. Treatment is relatively simple—urotropine or salol, with alkalis and excess of fluids, along with rest in bed.

Correspondenz-Blatt für Schweizer Aerzte.

February 16, 1918.

Significance of Carriers in Cerebrospinal Meningitis, Diphtheria and Typhoid Fever.—Silberschmidt states that carriers occur alike among the sick, convalescent and recovered patient, the nurse and other bystanders, and finally among the unknown. In scarlet fever and poliomyelitis we are quite ignorant as to who bears the disease germ, because the latter has never been isolated. We may speak of permanent carriers who have never been infected, temporary carriers or eliminators who have recently suffered from the disease and permanent carriers who have gone through the disease but cannot throw off the germs. The significance of carriers and methods of elimination vary with the disease. In cerebrospinal meningitis the acute course and high mortality make a strong impression on the public. The epidemiologist is impressed in a different fashion.

He notes that the earliest cases are deadly, but that the later are neither so acute nor so fatal. This is especially the case in barracks and among young adults. But in a community with many children things change greatly. As a rule an adult carrier infects a child. Thus in Silesia workmen from an infected district settled in a new community and communicated the disease to the children of their boarding masters. In France, reservists who had never been infected were sent home when the disease first appeared in the barracks and transmitted the disease to the children. We now know beyond doubt that the meningococcus is harbored in the nasopharynx. From 10 to 30 per cent of carriers never become infected. It is also well known that a subject with the disease seldom appears to convey it to others. In children's hospitals, even when no precautions are taken, spread of disease from the infected is almost unknown. The young recruit, coming to camp among conditions strange to him, is exposed to the weather conditions which would ordinarily cause catarrh of the nasopharynx. The time of year—February to March—is the era of exposure and propagation of disease. It has been shown that when a certain number of carriers enter a barracks the number of cases bear no relation to the number of carriers. The rounding up and internment of the latter seems to be an injustice, considering the very small number of cases which can be imputed to the presence of carriers. There is a marked factor of predisposition which explains the infrequency of infection in those directly exposed. As long as scores of carriers transmit little or no infection, the carrier problem in cerebrospinal meningitis becomes almost a dead letter. In diphtheria it is quite otherwise for here the carrier is justly accused of spreading the disease and is proportionately feared. Most physicians attach great importance to the bacteriological diagnosis, but cases occur in which laboratory and clinical finds do not correspond which cause a certain attitude of reservation. If in all such cases a second test were at once made the latter attitude would doubtless be changed. This refers to the initial diagnosis with especial reference to the indication for serotherapy. But in a case proved to be diphtheria no one attacks the great value of bacteriology because only through the laboratory can we determine whether a subject is cured and free from danger to others, and whether he still harbors germs and is a menace to others. But both the avirulent diphtheria bacillus and the pseudo diphtheritic bacillus constitute problems which can often only be solved by inoculation tests on guinea pigs. In clinical diphtheria there is no such germ as an avirulent Klebs-Loeffler bacillus, but the latter occurs at times in healthy men and those ill with maladies other than diphtheria, irrespective of past disease and epidemic incidence. If several hundred school children are examined at a given time a few may be found to harbor avirulent diphtheria bacilli. To what extent such children are potential carriers is unknown. They differ wholly in this respect from the healthy carriers of virulent germs discovered when the disease is prevalent and may be regarded as dangerous carriers. Neither local nor systemic treatment is certain of sterilizing a carrier and the only protection to give society is isolation, as in the case of the typhoid carrier.

Precipitate Labor and the War.—Rassauer during the past two years has seen many precipitate labors, even in primiparae. He associates the phenomenon with war emaciation and war amenorrhea, as having in part a common motivation, to wit, abnormal irritability of the nervous system.—*Muenchener medizinische Wochenschrift*.

Damage from War Diet.—Boenheim discusses war edema in which there is no cardiac or renal lesion but a secondary anemia. Victims had long been nourished almost exclusively on eggs and potatoes. Upon a diet of green vegetables with extra calcium and iron the disease promptly ceased. The author does not regard the condition as due to lack of vitamins. He believes that lack of certain protein is responsible; without this hemoglobin cannot be synthesized in the body. A needed "pyrrol ring" is supplied by plant legumes in the green state.—*Correspondenz-Blatt für Schweizer Aerzte*.

Book Reviews.

THE SURGICAL OPERATIONS ON PRESIDENT CLEVELAND IN 1893. By WILLIAM W. KEEN, M. D., LL.D., Emeritus Professor of Surgery, Jefferson Medical College, Major Medical Reserve Corps, U. S. Army. Philadelphia: George W. Jacobs & Co., 1917.

THIS is an interesting account of an operation for cancer performed on President Cleveland, no knowledge of which was allowed to come out during his lifetime. It is interesting to the profession and also bears testimony to the worth of the late President, both as a man and a statesman. Dr. Keen has done a public service by the publication of this little book on President Cleveland.

A MONOGRAPH ON THE EPIDEMIC OF POLIOMYELITIS (INFANTILE PARALYSIS) IN NEW YORK CITY IN 1916. Based on the Official Reports of the Bureaus of the Department of Health. Published under the Direction of the Department of Health of New York City, 1917.

THE epidemic of infantile paralysis occurring in New York last year stimulated a large addition to the already voluminous literature of this disease. Most of this was ephemeral in type, recounting already known aspects of the disease, but there emerged from this mass of material some contributions of solid value. The present volume may be taken as belonging to the latter class, representing as it does the seasoned observations and studies of the New York Health Department experts. Although names are modestly withheld, when we know that men like Park, Poor, Berg, Billings, Biggs, and Lederle are identified with this work we have sufficient assurance of its value.

After a brief survey of the historical aspects of the disease the question of causation is discussed, and the present status of the Flexner-Noguchi organism given. An exhaustive account of the post-mortem findings in forty cases is given; this agrees substantially with the pathology given by Wickmann, Harbitz, Scheel, and Straus. In this book, as would naturally be expected, the relation of the disease to the community is given more attention proportionately than the discussion of the disease itself, differing thus from the usual monograph on such a subject. But the general medical aspects are by no means neglected, forty pages, *e.g.* being devoted to diagnosis and forty-six to treatment. Not the least interesting part of the book is the appendix, which is a complete record of the New York epidemic, with many interesting pictures.

THE CONVERSION OF HAMILTON WHEELER. A Novelette of Religion and Love, Introducing Studies in Religious Psychology and Pathology. By PRESCOTT LOCKE. A Voluntary Contribution to the National Mental Hygiene Movement. Price, \$1.25 net. Bloomington, Ill.: The Pandect Publishing Company, 1917.

THIS is a book with a purpose! From the first line to the last we are not allowed to forget it. An emotional adolescent boy attends several of the spiritual debauches of an eminent revivalist (whom there is no difficulty in identifying), yields to a religious frenzy which finds its outlet in sexual immorality first, and finally in a near-psychotic episode. Through the judicious intervention of two alienists he is restored to normality. While the reviewer is heartily in accord with the purpose of this book he cannot help remarking that the heavy bricks of didactic psychopathology are too thinly joined by the mortar of narrative to make it interesting, and it will be an earnest reader indeed who follows the story to its end.

THE SENSE OF SIGHT. By FRANK NICHOLAS SPINDLER. Vice-President and Professor of Psychology and Education, State Normal School, Stevens Point, Wisconsin. Our Senses Series—GEORGE VAN N. DEARBORN, Editor. New York: Moffat, Yard and Co., 1917.

WHEN a reviewer reads in the editorial introduction that "the books are the best of their kind and are in a class by themselves, they are the standard authority for ordinary use. These volumes, when disposed as a red-backed set on one's library shelf will be a set of books to be proud of," he feels there is little he

can add. The possessor of such a monochromatous set is indeed a man set apart. But really there is much that the layman will find interesting and instructive in the present volume, and one is almost inclined to agree with the editor when he goes on to say, "the high school boys and girls and their fathers evenings and on Sundays, and their mothers at the club, all alike will think of them as highly valued friends, both wise and agreeable."

The book is one which the layman who wishes to possess or even to impress with a little learning may well add to his library.

AN INTRODUCTION TO THE PHYSIOLOGY AND PSYCHOLOGY OF SEX. By S. HERBERT, M.D., M.R.C.S. (England), L.R.C.P. (London). Author of "The First Principles of Heredity," "The First Principles of Evolution," etc. Containing 49 illustrations. Price, 5s. net. London: A. and C. Black, Ltd., 1917.

MANY are the books on sex, varying from the erotic exhibitions of the cheap professors who pander to the prurient curiosity of the proletariat to the ultra-scientific discussions of genuine physiology, but this book is a presentation of the facts of sex so that the intelligent lay reader can grasp them, and yet they are presented as coldly and dispassionately as if they were an explanation of the mechanisms of vision, we will say. An excellent thing, indeed! And Dr. Herbert has produced an excellent book, one to which the social worker, the minister, or the teacher can turn with assurance of enlightenment. We cannot imagine a more wholesome book to place in the hands of the adolescent, whose curiosity has been titivated by the whispering of schoolmates, whose imagination has been aroused by concupiscent best-sellers, and whose morbid inappreciation of physiological processes has been stimulated into dread by the dire prophecies of charlatans.

Dr. Herbert's views on sexual abstinence are the most sensible we have ever seen expressed in a book of this kind; and there are many other merits which lack of space forbids our enumerating.

HANDICAPS OF CHILDHOOD. By H. ADDINGTON BRUCE, Author of "Psychology and Parenthood," "The Riddle of Personality," etc. Price, \$1.50. New York: Dodd, Mead and Company, 1917.

THIS later contribution of this well-known author is a compilation in large part of articles which he has contributed to the pages of popular magazines. In this book a successful effort has been made to demonstrate the necessity of early and never-ending training of children in the moral sphere. All the mean, unpleasant traits of character and manner which men and women are afflicted with, and which detract from their success in life, both financially and socially, could in so many, many instances be traced back to faults of early training, due to indulgence of parents and those in authority during the child life of the suffering victim. These books of Addington Bruce bring to light the intense suffering undergone by people who have been badly trained in the training years, and they also show up the weakness of will, the lack of moral backbone, the love of luxury of mind and undisturbed life current of parents.

There is no use trying to evade the fact any longer that parenthood is a definite profession which needs a preparatory course of study and thought as well as any other profession entered into as a life work. Marriage may be nature's way of obtaining happiness and at the same time populating the world, but with this happiness goes certain serious duties that can no longer be side-stepped.

In this book the author has endeavored to make clear phases of childhood which can be more or less conquered by right training such as mental backwardness, mental and moral conditions surrounding the only child, the child who sulks, selfishness, stammering, bashfulness, indecision, and jealousy.

How much better it is to train children in the right and high-minded way, both for their good and the betterment of the world, than to have them as miserable, unhappy members of society, going, in later years, to psychoanalysts for the relief or cure of that which should have been eliminated from them as little children.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 25, 1918.

THE PRESIDENT, DR. HOWARD C. TAYLOR, IN THE CHAIR.

Conservation and Reclamation of the Civilian and Military Forces.—Major HARRY E. MOCK of Washington, D. C., made this contribution by invitation. He said that before reading his paper he wished to tell the story of Johnny Jones of Kokomo, Ind. Johnny left an orphanage at the age of sixteen years because he had a sister to support. He worked up to a position as trucker in the bolt factory, was satisfied with his job, and planned to be married, when he was drafted. While rescuing a comrade he was wounded, having both legs and his right arm shot off. For days he was too weak to think, and then came days when he was very despondent. Finally, he came to a reconstruction school. While waiting for the stumps to heal he began learning to write with his left hand. He then took a commercial course, and is now secretary to the president of the bank at home, making more per week than ever before. By physical reconstruction of the disabled men was meant the adopting of the very best medical or surgical procedures possible in order to obtain the greatest functional restoration in a diseased or injured organ or member of the body. Rehabilitation included the mental and physical training of the disabled individual so that he could again be established as a useful member of society, and included further supervision until he had secured a firm grip on life as represented by all its economic factors. All the nations engaged in this war have adopted methods of reconstruction and of otherwise reclaiming their disabled soldiers for the purpose of returning them either to the firing line once more or placing them back into industry. The Canadians had been forced to meet these problems during the last two years, for thousands of permanently disabled soldiers had been sent home. Canada had established reconstruction hospitals in every Province with curative shops in connection with them. It was voluntary with the discharged soldier whether he chose this opportunity for vocational training or not. The work both of training and of placing these men back into the occupations was left to civilian committees in each Province. In England the disabled soldier remained under military control until he had completed all medical and surgical treatment required in the hospital. France and Belgium had excellent systems of rehabilitation in certain centers. But a study of the plans for this work in all the countries showed that they were still incomplete and lacked the coordination necessary to make them efficient. In this country we would soon be facing the same problem. Congress had passed a very good war risk or disability insurance act which would enable us to carry on a very broad program of rehabilitation. This bill gave more or less control over the disabled soldier which would enable us to complete his rehabilitation. But the success or failure of our work rested with each individual. Unless the ambition and desire for this training was stimulated in the hearts and minds of the disabled men, the whole scheme would be a failure. Thus far the work in the surgeon general's office had been along the lines of studying and preparing for this great problem, arranging for the establishment of hospitals in every one of the sixteen draft districts of the country, and mapping out plans for curative shops and pre-vocational training. In making these plans it was realized that they must be made so comprehensive that they would fit in with the programs of existing civil organizations whose purposes were the same as theirs, namely, the placing of the disabled men back in civil life on a self-supporting basis.

At present this was a military problem and belonged to the medical department of the army. Closely allied to it was the same problem in the navy and in the industrial army. Later it became purely a civilian problem and entered the field of many federal, State, local, and private civilian organizations whose duty it would be to complete the rehabilitation. It was our duty

therefore to work out a plan that would not only be applicable to handicapped soldiers and sailors, but that would be applicable to the handicapped in the industrial army as well. A resumé of the plans for these crippled soldiers and sailors would illustrate the scope of the work.

The disabled soldiers on their return to this country would be received at a large central hospital. This hospital would undoubtedly be located on Staten Island. Here the patients would be thoroughly examined and each individual case passed on by both medical and vocational experts. From this central receiving point they would be distributed to (a) general hospitals; (b) special hospitals; (c) hospitals with special vocational schools; (d) direct home or to hospitals for incurables. In connection with each hospital, as an aid to medical care, there would be established gymnasiums, hydrotherapy and massage rooms, and mechanical appliances. Each hospital would have a curative shop where men could indulge in light work of various kinds. The purposes of these curative shops were: (a) to give mechanotherapy when indicated; (b) for their psychological effect; (c) for productivity and beginning vocational training when that was indicated. At all times a practical trend must be given toward employment. Pre-vocational schools would be open (a) for the purpose of curative therapy; (b) to teach new trades to those unable to take up their former occupation; (c) special schools for the blind, the deaf, the orthopedic and tuberculous cases, etc.; (d) for agricultural pursuits, which could be taught in some of the hospitals favorably located. Some of this vocational training must be given in already established schools, such as our State universities, where short courses could be arranged or regular courses adapted to the new needs. Others of the war injured, with no special training in any line of work and no special qualifications of entering vocational training, would best be placed directly into some industry or trade. Three of the best vocational experts in the country, representing commercial, professional, industrial, and agricultural schools, were serving as commissioned officers of the reconstruction staff of the surgeon general's office and were devoting their entire time to the development of this branch of the work. The widest publicity must be given to the proposed plans for reconstruction and later the public must be kept in constant touch with the actual work. The rehabilitated soldiers would need kindly advice and encouragement for some time to prevent them from deteriorating. The hospitalization and hero worship which these men would receive would tend to make retrogression easy and this must be counteracted by proper influences. Depending upon the length of the war, plans were being made to care for anywhere from 5,000 to 100,000 disabled soldiers who must be reconstructed and rehabilitated.

In civil life, we were told, there were between 600,000 and 700,000 industrial workers disabled as the result of accidents every year. Those disabled from preventable disease far exceeded this number. War had focussed attention on this great waste of human life. The time was ripe for our federal Government to put in force and administer a plan for this great conservation movement. Human conservation could be accomplished by health supervision, disease prevention, accident prevention, raising of the standards of medical and surgical practice, by educational campaigns on sanitation, living conditions and the allied subjects, and by the co-operation of all existing machinery.

The speaker then reviewed the various existing agencies that might be utilized, namely, the medical departments of the army and navy, the public health service. There should be an extension of this work to the industrial army employed in the military industries, to those employed in federal controlled industries, to employees in industries under federal contract, and to all civil industries necessary to the winning of the war. In civilian life much could be done for the furthering of this work by utilizing the State and municipal health departments, by utilizing State and federal inspectors, by educational campaigns, and by organized work such as that developed by the Food Conservation Bureau. The unsanitary conditions existing in many of our industries could no longer be ignored. Human conservation demanded the adoption of some such plan as this and the

winning of the war demanded some such plan as this.

Social Affairs for Disabled Soldiers.—Mr. CURTIS E. LAKEMAN of the Department of Civilian Relief, American Red Cross, Washington, D. C., made this address by invitation. He first referred to the plan described by the previous speaker, characterizing it as the ideal program of reconstruction peculiarly appropriate to the army of a democracy. The plan called for the participation of civilian agencies, and among them the American Red Cross had a definite part to play. The plans of the Red Cross did not in any way duplicate those of the Government, its field lying almost wholly in the social supervision of these men during the period of their readjustment to civil life. There was but one exception to this and that was the experiment station in the vocational training and employment of cripples established at No. 311 Fourth Avenue, New York, under the direction of Mr. Douglas C. McMurtrie, which exemplified the function of the Red Cross as an auxiliary of the army and navy. The Surgeon General and the Secretary of War had bestowed their approval on this school. The disabled soldiers and sailors on their return to this country would first be cared for by the military hospitals of the army and navy. But when they resumed their places in the community, after being discharged from further treatment and training in the Government institutions, the Red Cross would find an appropriate field for its activities in assisting these men temporarily during their period of adjustment to industry and normal life.

Many of the activities of the Red Cross were well known to the public, but it was not so well known that since August, 1916, the Red Cross had developed a system of service to the dependents of enlisted men which reached into every city and town in the country. The war risk insurance law of October 6 saw to it that the income of the soldier's family was kept up, but often more than money was needed. A family in trouble might need many services which the Government could not render as effectively as could a friendly neighbor, and there was no agency so well prepared to supply this friendly and patriotic spirit to each community as the Red Cross. The Red Cross called this part of its work "Home Service," which meant the conservation of American ideals of health, education, sanitation, housing and working conditions, relief in emergency, and the provision of a regular allowance to those who had no legal claim on the Government and nevertheless had heretofore been dependent on a soldier or sailor. In Manhattan and the Bronx alone four thousand families were being helped in this way. When the Government had rehabilitated a disabled soldier and placed him in a suitable employment his problems and difficulties of readjustment became the concern of the Home Service. He needed constant personal encouragement, help in finding congenial surroundings, and assistance in meeting and overcoming obstacles. A condition of permanent stability in the reunited family must be maintained, and a continuous effort made to restore self-confidence, self-reliance, and ambition. When everything possible had been done for the rehabilitated man and his family, something remained to be done with the employers. They should be encouraged to provide proper opportunities for handicapped men and to exercise forbearance in their dealings with them. Last, but not least, it was the first duty of the Red Cross and of all other agencies truly interested in the rehabilitation of disabled soldiers to create the most wholesome public sentiment, to the end that every effort to become self-supporting might be encouraged and that everything possible might be done for the disabled soldiers returning from the front.

Vocational Reeducation of the War Cripple.—Mr. DOUGLAS C. MCMURTRIE, director of the Red Cross Institute for Crippled and Disabled Men, described the work that the Red Cross Institute planned to do and illustrated it with lantern slides. He stated that up to the present time the whole tendency in the way of making amends for industrial accidents had been in paying off some money indemnity. It had remained for the present war to bring about changes in this attitude. This was well brought out by the pictures showing the work being done abroad in the reeducation and rehabilitation of crippled and disabled men. The speaker then described the reconstruction work now being carried on

at Roehampton, England, and in several Continental reconstruction schools. When a man was an expert in any particular line of work the attempt was made to raise him a grade in his own line of work. Provision was made for special training in almost every line of industry. On the other side, a good deal of attention was given to teaching cobbling, as this enabled a man to open a shop of his own and to make a comfortable competence. Cobbling was found to be a useful trade in Canada, but it did not promise so much in this country. As an illustration of what could be done pictures were shown of soldiers with both legs amputated at the hips. Some of these men became expert leather workers and saddlers, and others were taught the more expert processes of tailoring. Wherever possible cripples were employed as teachers. In Canada it had been found that in order to be thoroughly successful the teacher must have been overseas himself. The man who "had been through the mill" himself had much more influence and offered a greater inspiration to those who were learning than did one who lacked this experience.

There were a number of these vocational schools in Canada; one at Winnipeg accommodated two or three hundred men. In these schools special attention was given to teaching the making of artificial limbs. In making provision for prosthetic appliances two sets were usually supplied, one constructed for efficiency in the workshop and one constructed esthetically for wear when working hours are over. The method of using an artificial limb or appliance was practically always taught by a man who was wearing such an appliance. The occupations taught in these schools, included tailoring, cobbling, carpentry and cabinet work, the making of artificial limbs, electrical maintenance and repairs, the making of submarine fittings, coppersmithing, welding, blacksmithing, typewriting, stenography, book-keeping, switchboard operating, etc. The idea was to fit the men so that they would fit into a local labor market. One of the most essential things to be done was to keep the men who had been on farms still on the land. It had been found that after vocational training a man could do his own farm work no matter how badly crippled he was. The American Red Cross was trying to contribute to the French reeducational system up-to-date agricultural machinery so that a man could depend upon skill and device as a substitute for his lost strength. In Alberta, Canada, the reconstruction work was as good as anywhere in the world. They were getting 95 per cent. of the men who would profit by vocational work to take it up voluntarily. In the United States it had been the intention of the Government from the first to reeducate cripples, but there had been considerable delay in getting the work under way. In the meantime several private agencies had become interested and had offered to contribute, among them Jeremiah Milbank, who had offered the Red Cross sufficient money to start a school at once. As soon as this subject was discussed it was seen that this was not only a question of the soldier cripple but that it concerned other cripples as well, and for this reason the Red Cross had started its activities. When the war cripples began to return the institute would be in a position to take them in and deal intelligently with them. At the present time the institute was taking care of the cripples of industry and those in charge would be glad to have brought to their attention any case that would be helped by reeducation. It was their object to place cripples in occupations where their handicap would not be a drawback. Where a man could not be fitted to his former employment without such a handicap he would be taught a new trade or occupation. The classes were being started at the present time in the old building of the College of Physicians and Surgeons, at Twenty-third Street and Fourth Avenue, New York. They hoped to do considerable experimental work in artificial limbs.

At the present time the scheme for reeducational work was under discussion in Washington and the effort was being made to prevent the work from becoming localized. In France the cripple's care depended upon the locality from which he came. If there was work there that he could do, he profited; if there was none he suffered. There was no doubt that the national plan was most desirable. It seemed probable that the

reconstruction work would be handled from the surgeon general's office and would be conducted in various reconstruction hospitals throughout the country.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Regular Meeting, Wednesday, February 13, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

Plastic Repair of Oral Mutilations from War Injury or Operative Attack.—Dr. JOHN B. ROBERTS said that his paper might perhaps find justification in the frequent avulsions of military surgery, the burnings with liquid fire in war, and the operative mutilations demanded by delay in radical treatment of malignant disease. While some difference in detail occurred in the repair of lesions of lips, cheeks, and jaws from the causes mentioned, the principles of the surgeon's reconstructive acts and the steps through which the human organism responded to his desires were said to be essentially the same. A surprising degree of ignorance, Dr. Roberts observed, existed regarding the availability and success of treatment for such forms of facial deformity, such ignorance existing not only in rural populations but in large cities as well. Congenital malformations, like harelip and cleft palate, also cicatricial distortions from slow healing of burns and crushing injuries were seen at metropolitan hospitals for treatment, months, even years, after the precious moment when the aid of corrective surgery or dentistry should have been sought. The appreciation of the value of early plastic aid, Dr. Roberts said, was gradually being instilled into the minds of surgeons by the lessons of the present European war. The energy exhibited by the contracting force of fibrous tissue when it replaced granulation tissue in wounds was said to be astonishing. Carrel and deNoüy had shown that when open wounds were compelled by infection to heal through the conversion of granulation tissue into scar tissue, the major part of the closure was effected by dragging the boundaries of the ulcer toward a central point. Thus it was that the epidermization was reduced to a minimum and the cutaneous defense against ingress of microorganisms from without re-established. The effect of this interstitial contraction on the surrounding and underlying structures was lamentably evident. Slow healing of wounds due to injury, tardy cure of ulcers left by suppuration of tissues killed by fire, electrolysis, or chemical action, left eversion of lips and eyelids, closure of orifices of mouth and nose, strictures of ducts, and produced adhesions that restrained the movements of joints.

Major HUNTER W. SCARLETT said that the pictures shown by Dr. Roberts reminded him of the cases seen at the American Ambulance in Paris in the first two years of the war, the only difference being that the war wounds were infected, which delayed reparative work, in some cases, for from five to twelve months. He had been impressed in such work with the importance of making flaps as large again as would ordinarily be thought necessary for filling in of the gap, also of making their bases very large, with sufficient subcutaneous tissue to insure nourishment and prevent superficial gangrene or deep sloughing. In two cases in which these precautions were not observed sloughing of flaps occurred. More success had been obtained in the use of the pedunculated flap than in those taken from other parts of the body. An astonishing fact was that so large an amount of tissue might be lost and the membrane brought to almost its normal position. In one case in which the whole side of the face had been shot away, the bony structures only remaining, the wound had cicatrized down to possibly an inch in diameter. Nature did much for these wounds; in a number of instances, after making the wound surgically clean and approximating the tissues, it had been left exposed to the air except for a covering of gauze.

Captain BRUSH, appreciating the courtesy of Dr. Roberts in his invitation to the members of the military surgery class to discuss his paper, felt that he could offer nothing of interest from personal experience, but referred to the technique of Morestin whom he had seen operate in Paris. In operations under local anesthesia only three persons took part, Morestin himself,

his assistant, and the hospital nurse. In operations under general anesthesia the anesthetist made a fourth. The instruments were laid in a large open box; very few towels were about. The manipulations of the operator were done with great rapidity; the flaps were brought up as far as they would bear the tension and were then united. The sutures used by Morestin were almost exclusively silkworm gut and this was darkly stained to be easily seen. The sutures, he said, were passed through the thick edge of the flap, the Hagedorn needle being used; the ends were rapidly tied and allowed to hang long. These were gathered up by the assistant and held until the completion of the operation.

Dr. L. J. HAMMOND asked Dr. Roberts how he secured mucous membrane lining for the newly formed lips and cheeks in cases in which there had been great loss of substance. He had found it essential to employ mucous membrane lining in order to obtain an approximation to normal contour of the lip.

Dr. C. B. LONGENECKER inquired how Dr. Roberts determined the interval of time when the wound in a malignant case might be safely closed, observing that if any of the malignancy remained the plastic work was, of course, useless.

Dr. ROBERTS, in closing, said that in operating upon a malignant case he endeavored to get far beyond the area of the disease, agreeing with Dr. Longenecker that if this were not possible, plastic work was inadvisable. Replying to Dr. Hammond, he said he sometimes tried to save mucous membrane for lining the lip or cheek; he did not, however, pay so much attention to this matter as did some operators, since he usually tried to get enough skin or muscle turned into the cheek to offset any probable contraction. He agreed with Major Scarlett that Nature could do much more for these wounds if they were lightly dressed. A big poultice, he said, soon became saturated with fluid and in reality formed a pus poultice. His endeavor was to dress all his operations dry; often he put on no dressing at all if the lines of the incision were not too close to the orifice of the mouth or nose where it would become contaminated. His standing rule was that his assistant should not wash the area, except with a damp cloth in the region not operated upon.

An Analysis of Fourteen Hundred Cases of Cancer Treated by Electrothermic Methods or in Combination with Operative Surgery, X-Rays, or Radium.—Dr. WILLIAM L. CLARK said that electrothermic methods of treatment of cutaneous cancer had been found to be more uniformly reliable than other procedures. This was also true of cancer of the lower lip and oral cavity; but operative surgery, x-rays, or radium might be used to advantage when metastasis had occurred. When glands or large blood-vessels were involved electrothermic methods could not be used with safety in the region of the blood vessels. Operative surgery and the x-ray were usually preferred in mammary cancer, but a breast might be removed by electrothermic methods. Operative surgery, radium, or both in combination, ordinarily seemed best in cancer of uterine cervix, but electrothermic methods were also of value. Cancer of the bladder or rectum, unless seen very early, was hopeless. If seen early electrothermic methods offered the best chance of success. Electrothermic methods were successful when the disease was localized, and they had the advantage over other methods in that the diseased tissue was entirely destroyed with one treatment, blood and lymph channels were sealed, and superior cosmetic results were obtained. The successful treatment of cancer, generally speaking, he said, was the intelligent use of the methods best suited for the individual case; or, when indicated, the use of combined methods.

One Hundred Cases of Cancer of the Uterus Treated by Radium.—Dr. JOHN G. CLARK said that during the last three years he had had under treatment considerably over 100 cases of inoperable cancer of the cervix. One hundred of these had been available for statistical study. So long as cancer was within operable bounds surgical treatment had been employed. The treatment of these inoperable cases with radium had been begun on purely the palliative basis and so continued because it had been realized that no case was a cured case under five years and in none of these cases has that length of time elapsed. The hope was expressed and, indeed,

the belief, that after the lapse of five years there would be a distinct percentage of these patients still alive and apparently free from the growth; because there were now quite a number beyond the two-year period without signs of local cancer. With Dr. Keene he had been watching the cases with a great deal of interest. The patients returned from time to time for examination; consequently the cases presented were those which had been controlled. One very interesting case was cited in which two and a half years had elapsed since the beginning of treatment. The woman weighed 240 pounds and was a diabetic—therefore a serious surgical risk. The radium had been applied twice and her symptoms, short of the discharge, had ceased. If metastasis was present radium did not cure. The great danger in the use of radium, Dr. Clark believed, was that the striking case impressed one with such force that one was likely to anticipate better ultimate results in all cases than might be realized. The argument for the use of radium, it was emphasized, was purely that of palliation with a strong degree of hope of cure, because the author was constantly seeing patients two, and two and a half years after treatment with no return. The average stay in the hospital was said to be three days. The free patient could have the treatment while there was bed space just as readily as the one who paid.

Dr. L. W. KOHN said that of all malignant conditions perhaps cancer of the stomach was the most difficult to treat, because of the difficulty of access to the organ. In his work they had endeavored to recognize the condition early so that the patient might be referred promptly for surgical treatment. When metastasis had occurred, operation, of course, was unavailing. Then the only resort was to try to give the patient some degree of comfort in amelioration of symptoms and to offer psychic encouragement. A trial of radium, he thought, might also be made. Reference was made to the fact that the Mayo brothers had treated well advanced cancer at the cardiac end of the stomach by the use of radium capsules inserted by means of the sound, and that they claimed a certain amount of benefit.

Dr. G. C. BIRD thought that unquestionably the electrothermic, coagulation, and desiccation methods should be used in some of the forms of epithelioma referred to the roentgenologist. After destruction of the growth the x-ray was used to advantage in preventing metastasis. Dr. Bird had had no experience with the treatment of cancer of the uterus with radium. He had seen fibroids of the uterus in which he had suspected malignant disease, treated by the Percy cautery, and one of this number remained cured for two years. In cases of malignancy of the uterus he would not think of depending upon the x-ray for cure.

Dr. BARTON COOKE HIRST inquired regarding Dr. Clarke's experience with treatment by radium of recurrence of cancer of the uterus. Personally he had been discouraged with the results. In many cases of recurrent cancer, after the complete removal of the uterus, radium treatment had been invariably unsuccessful except in one case. One successful case, however, argued for the routine adoption of the method. In one case of very bad recurrence operated on two years ago last summer the patient within six months had recurrence in the vaginal scar as big as his fist. He had referred her to Dr. Newcomet, and she was now, after having had seven or eight applications of radium, apparently entirely free from malignancy.

Dr. G. BETON MASSEY said that the two very convincing papers led him to plead for the consideration of cancer as a parasitic disease, although the pathologists had not so determined. Approaching the subject from this standpoint and acting upon this probability would give hope in the early treatment and patients would seek aid earlier. The methods outlined by Dr. William L. Clark, he said, made possible a frontal attack on these growths, which was not possible with the knife. In the knife treatment of cancer the surgeon necessarily must not touch the growth, and none of the infected cells must rest upon the wound. With the ionic and electrothermic methods and with radium a frontal attack was possible, going through the disease and reaching the periphery and sealing it against reimplantation of the germ. It seemed to the speaker

that there should be more exactitude in the use of terms; while radium was so successful in uterine cases it was not in any sense surgery as were other processes mentioned.

Dr. C. B. LONGENECKER, referring to Dr. Clark's statement of the large number of cases of cancer of the uterus which were inoperable when first seen, said that for the last five or ten years there had been an effort made in the State, County and other societies to train physicians to the early recognition of cancer. Results, however, had not been gratifying, since there were almost as many cases of inoperable cancer as before. Dr. Longenecker did not regard the application of radium as quite so simple a matter as indicated by Dr. Clark; not every case, he thought, could stand the same dosage; he thought it advisable to try out the resistance of the individual patient before giving the massive dosage. Besides the use of radium in the inoperable cases he referred to other means of value. At the Jefferson Hospital there was used the Coolidge tube by which an intensified x-ray with an absolutely measured dose was possible. A combination of the radium treatment and the Coolidge x-ray, he thought, was often an improvement upon radium alone. While there was apparently not much difference in the radiation of the two, there seemed to be something reached by one not accomplished by the other. Frequently they used also one of the electrical modalities in connection with the radium or the Coolidge tube.

Dr. F. HURST MAIER said that all were impressed with the very conservative analysis given by Dr. Clark of his series of cancer of the uterus. If radium could do nothing more in these inoperable cases than check hemorrhage, decrease the discharge, and relieve the pain in the percentages given, the treatment was indeed of much value. He asked whether it was not advisable, after the surgical removal of the uterus for cancer, to give two or three treatments of radium at monthly intervals. Such application, it would seem, would destroy any foci of malignancy and yield a larger percentage of permanent cures.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

Clarksburg, November 21, 1917.

ANATOMY.

1. What blood vessels pass to and from the liver?
2. In an amputation of the forearm 3 inches above the wrist, what arteries will it be necessary to tie, and of what are they branches?
3. What cranial nerve has the widest distribution, and give the four principal points of distribution.
4. What muscles form the tendo Achillis, and where is the tendon inserted?
5. What is the chief difference between the male and female pelvis?
6. Name the abdominal viscera wholly covered with peritoneum and those partially covered.
7. Name the regions of the abdomen.
8. Locate and briefly describe the gall-bladder.
9. Name the subdivisions of the alimentary canal, and give the name and location of the various glands found in the small intestine.
10. Give the classification of joints, with an example of each.
11. What bones make up the pelvis? Give the gross anatomy of the bony pelvis.
12. Give the origin and insertion and blood and nerve supply of the humeral biceps muscle.

PHYSIOLOGY AND HISTOLOGY.

1. Give briefly but accurately the structure of an artery, and describe its physiology.
2. Describe the physiological symptoms of Bell's paralysis.
3. If the right optic tract is cut what will be the effect? Define the conditions and trace good fibers.
4. What is lymph? How do lymphatics begin? Describe a lymph gland.
5. Mention some important characteristics of the pulse in health and in disease.

6. What is the source of animal heat? How is the temperature of the body maintained?
7. What is the composition and action of the bile?
8. Food—divided into how many classes? Give example and chemical composition of each.
9. Discuss physiologically, bacterial action in the alimentary tract.
10. Classify and give function of white blood corpuscles.
11. Describe the heart sounds; what causes them?
12. Give the physiological action of the pneumogastric nerve.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. What is a poison? How may poisons be classified? Give the manner of action of each class.
2. How would you conduct an autopsy for the purpose of testing for arsenic in the stomach, intestines, and tissues?
3. Give the difference between a physical and a chemical change, with an example of each.
4. Define (a) atom, (b) molecule, (c) a mechanical mixture, and (d) a chemical compound.
5. What are the antidotes for poisoning with (a) copper sulphate, (b) nitric acid, (c) tartar emetic, (d) carbolic acid, (e) bichloride of mercury?
6. In what respects does mother's milk differ from cow's milk?
7. In what part of the digestive tract are proteins digested, and what are the active agents concerned?
8. Give the distinguishing marks between ante- and post-mortem wounds.
9. How can you tell whether an infant has been born dead or died after birth?
10. Define criminal abortion.
11. What is meant by dying declaration and what points must be fulfilled before same has any legal significance?
12. Give the chemical reasons why diabetics should abstain from starchy foods.

MATERIA MEDICA AND THERAPEUTICS.

1. Strychnine: Derivation, dose, and physiological action.
2. Discuss vaccine and serum therapy, naming three vaccines.
3. Mention two heart stimulants that act quickly; discuss their mode of action, giving dose.
4. Write a prescription for acute catarrhal dysentery, using not less than three drugs.
5. Write a prescription for incontinence of urine in an old person, using at least two drugs.
6. Discuss the use of potassium iodide.
7. Aspirin: Give origin, dose, and physiological action.
8. Describe fully the way a saline cathartic acts. Give three examples.
9. How would you treat a case of failure of respiration under ether anesthesia?
10. Write a prescription for the treatment of simple stomatitis, containing at least two drugs and a menstruum.
11. Discuss the physiological effect of belladonna and its derivatives.
12. Name five of the most dangerous poisons, and their antidotes.

ANSWERS.

ANATOMY.

1. The hepatic artery and portal vein pass to the liver; the hepatic vein passes from the liver.
2. In an amputation of the forearm three inches above the wrist, the following arteries should be tied: Radial (branch of brachial), ulnar (branch of brachial), anterior interosseous (branch of ulnar), posterior interosseous (branch of ulnar).
3. The tenth cranial, or pneumogastric, nerve has the widest distribution; four principal points of distribution are: Heart, lungs, stomach and larynx.
4. The tendo Achillis is formed by the gastrocnemius and soleus; its tendon is inserted into the lower part of the posterior surface of the os calcis.

5. The chief differences between the male and female pelvis are thus tabulated in Morris's *Anatomy*:

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischiopubic rami more everted.	Margins of ischiopubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater.

6. (a) *Viscera wholly covered with peritoneum*: Liver, stomach, spleen, jejunum, ileum, transverse colon, sigmoid flexure, upper part of rectum, uterus, and ovaries.

(b) *Viscera partially covered with peritoneum*: Duodenum, ascending and descending colon, middle part of rectum, and bladder.

7. *Names of the regions of the abdomen*: Right hypochondriac, epigastric, left hypochondriac, right lumbar, umbilical, left lumbar, right iliac, hypogastric, and left iliac.

8. The gall bladder is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of the duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage. It is about four inches long, and holds about one ounce. Its duct passes from the neck of the gall bladder downward, backward, and to the left to join the hepatic duct.

9. *Subdivisions of the alimentary canal*.—Mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, ileum), large intestine (cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, rectum). *Glands in small intestine*: *Glands of Lieberkuhn*, in all parts of small intestine; *Brunner's glands*, in duodenum and beginning of jejunum; *solitary glands*, in all parts of small intestine; *Peyer's patches*, in ileum chiefly, also in lower part of jejunum, occasionally a few are found in the duodenum.

10. *Classification of joints*: (1) *Synarthrodial* (or immovable), as the sutures of the skull; (2) *amphiarthrodial* (or slightly movable), as the symphysis pubis; (3) *diarthrodial* (or freely movable), as the shoulder joint.

11. The pelvis is made up of the two ossa innominata (each of which is composed of ilium, ischium, and pubic bone), the sacrum, and the coccyx. The pelvis is divided into two parts by a plane passing through the sacral promontory, the iliopectineal lines, and the upper border of the symphysis of the pubis. The space above this plane is called the false pelvis, and belongs to the abdomen; below this plane is the true pelvis. The pelvic outlet presents three prominences, the tuberosities of the ischia and the tip of the coccyx. Beneath the symphysis is the subpubic arch; and behind the tuberosities of the ischia are the sacrospinous notches. There are differences in the male and female pelvis; see above, question 5.

12. *BICEPS*. *Origin*: Coracoid process of scapula and upper margin of glenoid cavity of scapula. *Insertion*: Back part of tuberosity of radius. *Blood supply*: Muscular branches from the brachial artery. *Nerve supply*: The musculocutaneous (from the brachial plexus).

PHYSIOLOGY AND HISTOLOGY.

1. "A typical artery consists of three coats: an internal, the *tunica intima*; a middle, the *tunica media*; an external, the *tunica adventitia*. The internal coat consists of a structureless elastic basement membrane, on the inner surface of which rests a layer of elongated spindle-shaped endothelial cells. The middle coat consists of several layers of circularly disposed, non-striated muscle-fibers, between which are networks of elastic fibers. The external coat consists of bundles of connective tissue of the white fibrous and yellow elastic varieties. Between the external and middle coats there is an additional elastic membrane. In the small arteries there is but a single layer of muscle-fibers. In the large arteries the elastic tissue is very abundant, exceeding largely in amount the muscle-tissue. It is also more closely and compactly arranged. The external coat is well developed in the large arteries. In virtue of the presence in their walls of both elastic and contractile elements, the arteries possess the two properties of elasticity and contractility."

"The functions of the arteries are as follows: (1) to distribute the blood to all regions of the body; (2) to accommodate varying volumes of blood; (3) to convert the intermittent flow of blood as it leaves the heart into a remittent and finally into a continuous and equable flow as it passes into the capillaries; (4) to regulate the volume of blood delivered to an organ in accordance with its functional activities, and (5) to present that degree of resistance necessary to the maintenance of the normal blood pressure, through the activities of the muscle fibers in the walls of the arteries." (Brubaker's *Physiology*).

2. *Physiological Symptoms of Bell's Paralysis*: "When the seventh cranial nerve is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums." (Kirkes' *Physiology*).

3. Division of the right optic tract will produce hemipopia in the temporal half of the right eye and the nasal half of the left eye, with left lateral hemianopsia. The good fibers will all proceed from the left optic tract which supplies the temporal side of the left retina and the nasal side of the right retina.

4. **LYMPH. Origin**: There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence. **Description**: Lymph is a colorless, albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. **Composition**: Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea, fat. **Function**: To provide cells and tissues with materials necessary for their growth, repair, and functional activities; and to receive and carry away their waste products.

Lymphatics begin (1) in closely meshed networks, or (2) in irregular lacunar spaces between the various structures of which the different organs are composed.

Lymphatic glands. "The basis of all lymph glands is the so-called lymphoid tissue, which consists of retiform or adenoid tissue with lymph corpuscles occupying the meshes of the network. The lymph glands are small rounded bodies placed in the course of the lymphatic and lacteal vessels, through which the lymph and chyle pass on the way to the thoracic duct. They are collected in groups, such

as the mesenteric, portal, bronchial, splenic, cervical, lumbar and inguinal glands. The afferent lymphatics enter the glands on the outer or convex surface, and emerge as the efferent vessels at the hilum. Each gland is surrounded by a fibrous capsule, which passes into the interior as the trabeculae or septa. The trabeculae pass one-third or one-fourth of the way into the gland (the cortex), dividing it into oval compartments, whilst in the central portion they join together and form small compartments of an irregular shape (medullary portion). The capsule and trabeculae are formed of fibrous tissue and nonstriated muscular tissue, and carry the vessels which enter the gland, and are distributed to the lymphoid tissue of the gland. The compartments of the cortex contain oval masses of lymphoid tissue which do not completely fill them, and which form the lymph follicles of the cortex; the medullary portion contains irregularly shaped or elongated masses called the medullary cylinders. The space left free between the lymph follicles and the cortical trabeculae, and between the medullary cylinders and the trabeculae, forms the *lymph sinus*. The lymph path or sinus is occupied by coarse retiform tissue. The afferent lymphatic vessels, having entered at the cortex at the external surface, open into the lymph sinuses of the cortex, then the lymph passes into the lymph sinuses of the medulla, and leaves the gland by the efferent lymphatics at the hilum. The passage of the lymph through the sinuses is delayed by the reticulum, that any foreign bodies or inflammatory products may be arrested in the passage." (Ashby's *Notes on Physiology*).

5. *Characteristics of the pulse to be noted*: The frequency, the strength, its regularity or irregularity, its tension, its compressibility, its rhythm, and whether it is large, full, or small.

6. The normal temperature of the body is maintained by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: Oxidation; muscular action; the action of the glands, chiefly of the liver; the food and drink ingested; the brain; the heart; and the thermogenetic centers in the brain, pons, medulla, and spinal cord.

"The immediate source of the body-heat is to be found in the chemical changes which take place in all the tissues and organs of the body. Each contraction of a muscle, each act of secretion, each exhibition of nerve-force, is accompanied by the evolution of heat. The chemical changes are for the most part of the nature of oxidations, the union of oxygen with the elements, carbon and hydrogen, of the food principles either before or after they have become constituents of the tissues. The ultimate source of the body-heat is the latent or potential energy in the food principles, which was absorbed from the sun's energy and stored up during the growth of the vegetable world. In the metabolism of the animal body the food principles are again reduced through oxidation, directly or indirectly, to relatively simple bodies, such as urea, carbon dioxide, and water, with a liberation of a large portion of their contained energy which manifests itself as heat and mechanical motion."—(Brubaker's *Physiology*).

7. *Composition of bile*: Water and solids; the latter, about 15 per cent, consist of sodium taurocholate, sodium glycocholate, mucin, bile pigments (bilirubin and biliverdin), lecithin, cholesterolin, neutral fats, and inorganic salts (NaCl, KCl, and phosphates).

The *physiological action of the bile* is: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis; and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterolin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it aids the pancreatic juice in digesting protein; (8) it has a very feeble antiseptic action.

8. *Foods are classified*:

I. Inorganic. { Water.
 { Salts.

11. Organic. { Non-nitrogenous. { Carbohydrates.
 { Fats.
 { Nitrogenous—Proteids.

Examples of each: *Carbohydrate*, sugar and starches; *Fat*, fat of meat, and butter; *Proteid*, flesh of animals, and white of eggs; *Salt*, sodium chloride, and calcium phosphate.

The *carbohydrates* consist of carbon, hydrogen and oxygen, the two latter being in the proportion to form water. *Fats* consist of carbon, hydrogen, and oxygen, the proportion of oxygen being less than sufficient to convert all the hydrogen into water. *Proteids* consist of carbon, hydrogen, oxygen, nitrogen, sulphur, and sometimes other elements.

9. *Bacterial action in the alimentary tract*: "The gastric juice is an antiseptic; the pancreatic juice is not. An alkaline fluid like pancreatic juice is just the most suitable medium for bacteria to flourish in. Even in an artificial digestion the fluid is very soon putrid, unless special precautions to exclude or kill bacteria are taken. It is often difficult to say where pancreatic action ends and bacterial action begins, as many of the bacteria that grow in the intestinal contents (having reached that situation in spite of the gastric juice) produce enzymes which act in the same way as the pancreatic juice. Some form sugar from starch, others peptone, and amino-acids from proteins, while others, again, break up fats. There are, however, certain actions that are entirely due to these putrefactive organisms. (i) On *carbohydrates*. The most frequent fermentation they set up is the lactic acid fermentation: this may go further and result in the formation of carbonic acid, hydrogen, and butyric acid. Cellulose is broken up into carbonic acid and methane. This is the chief cause of the gases in the intestine, the amount of which is increased by vegetable food. (ii) On *fats*. In addition to acting like lipase, they produce lower acids (valeric, butyric, etc.). The formation of acid products from fats and carbohydrates gives to the intestinal contents an acid reaction. Recent researches show that the contents of the intestine become acid much higher up than was formerly supposed. Organic acids do not, however, hinder pancreatic digestion. (iii) On *proteins*. Peptones, amino-acids, and ammonia are produced; but the enzymes of these putrefactive organisms have a specially powerful action in liberating substances having an evil odor, such as indole, skatole, and phenol. Indole and skatole originate from the tryptophane radical of proteins. There are also gaseous products in some cases. Ammonia-producing organisms flourish best in the lower regions of the small intestine; the ammonia neutralizes the organic acids produced higher up, and in the large intestine the contents have in consequence an alkaline reaction. If excessive, putrefactive processes are harmful; if within normal limits, they are useful, helping the pancreatic juice, and, further, preventing the entrance into the body of poisonous products. It is possible that, in digestion, poisonous alkaloids are formed. Certainly this is so in one well-known case. Lecithin, a material contained in small quantities in many foods, and in large quantities in egg-yolk and brain, is broken up by the pancreatic juice into glycerophosphoric acid, fatty acids, and an alkaloid called choline. We are, however, protected from the poisonous action of choline by the bacterial enzymes, which break it up into carbonic acid, methane, and ammonia."—(Halliburton's *Physiology*.)

10. *White blood corpuscles* are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

11. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter.

The causes producing the first sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall. The second sound is caused by the vibration due to the closure of the semilunar valves.

12. *Physiological action of the pneumogastric nerve*: "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) motor influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) sensory and, in part, (3) vasomotor influence, to the same regions; (4) inhibitory influence to the heart; (5) inhibitory afferent impulses to the vasomotor center; (6) excitatory to the salivary glands; (7) excitomotor in coughing, vomiting, etc."—(Kirkes' *Physiology*.)

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. A *poison* is a substance which, on being in solution in or acting chemically upon the blood, causes death or serious bodily harm. *Classification*: There are many classifications given, but not one of them is entirely satisfactory. That of Witthaus is into corrosives and poisons proper, the latter being subdivided into mineral poisons, vegetable poisons, animal poisons, and synthetic poisons.

A *corrosive* is a substance capable of producing death or injury by its chemical action upon a tissue with which it comes in contact. Corrosives and poisons also differ in other respects. Corrosives act upon dead and living tissue alike, while poisons, as a rule, do not. The violence of corrosion is directly proportionate to the degree of concentration, while the action of poisons depends upon the actual quantity absorbed, but in no wise on the degree of concentration of the solution taken. A corrosive may kill by destroying the skin, producing an injury resembling a burn; the poisons, if applied to the skin, act only when absorbed.

2. The following portions of the cadaver should be preserved for analysis in cases of suspected homicide by poison: "The alimentary canal from the cardia to the middle of the rectum, unopened, and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder. Any suspected food articles, and any obtainable vomited matter, are to be also preserved. They are to be placed in clean and new glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself. The post-mortem appearance in acute arsenical poisoning are confined to the stomach and intestines. The stomach is inflamed, whether arsenic has been taken by the mouth or by other channels of absorption. The mucous surface is coated with a layer of mucus, tinged with blood or bile, and sometimes containing white crystals of As_2O_3 or green particles of Paris green. The color of the mucous membrane is brownish red, interspersed with darker streaks or patches between the rugæ. The small intestines are sometimes inflamed throughout their length, but more usually the inflammation is limited to the duodenum."—(Witthaus' *Essentials of Chemistry and Toxicology*.)

3. A *physical change* is such a change as does not alter the composition of a substance; a *chemical change* does alter its composition. "A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism, when under the influence of an electric current. Under the influence of these physical forces the iron suffers no change in composition, and on cessation of the action of the inciting force, the iron returns to its original condition. But if the iron is heated in an atmosphere of oxygen both the iron and a part of the oxygen disappear, and a new

substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action*, causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action."—(Witthaus' *Manual of Chemistry*.)

4. An *atom* is the smallest quantity of an element which can enter into the composition of a molecule.

A *molecule* is the smallest portion of a substance (element or compound) which can exist free.

A *mechanical mixture* is a product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds.

A *chemical compound* is a substance made up of two or more elements chemically united with each other in definite proportions.

5. *Antidote* for poisoning by *copper sulphate*, is solution of potassium ferrocyanide; for *nitric acid*, magnesium oxide or hydroxide; for *tartar emetic*, tannin; for *carbolic acid*, sodium sulphate, alcohol; for *bichloride of mercury*, white of egg in moderate amount.

6. Woman's milk contains more solids, less protein, and more sugar than cow's milk.

Cow's Milk. Human Milk.

Water	87.41	87.21
Total solids	11.59	12.71
Fat	3.66	3.78
Milk-sugar	4.92	6.04
Casein	3.01	1.03
Albumin	0.75	1.26
Proteins	3.76	2.29
Ash	0.70	0.31

7. Proteins are digested in the stomach and the small intestine; in the stomach by the action of the acid pepsin; and in the small intestine by the action of the trypsin of the pancreatic juice, and erepsin of the succus entericus.

8. A *wound inflicted during life* is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

In *post-mortem wounds*, the reverse of this will be found.

9. "The *general appearance* of a child that has been *born alive* at full term and respired is something like the following: The remains of the vernix caseosa are usually, seen under the axilla, and behind the ears. The eyes remain partly open, and cannot be permanently closed. The ears are not so close to the sides of the head as is the case in children born dead. The hair is perfectly dry and clean, and the swelling at the back of the head (*caput succedaneum*) is more prominent than in the still-born. In the *dead-born* infant who has died immediately before its birth the vernix caseosa will be found, more or less, over its entire body. The eyes are closed and the ears are in close apposition to the head. The eyelids when raised close again. The mouth is closed, and from the nostrils is often observed exudation of watery blood. The hair is glued to the head. The thorax is unexpanded and flattened, and the lungs are situated at the posterior part of the thoracic cavity; they are greater in length than in breadth, and their margins are rounded; upon pressure no crepitation is elicited. Within the trachea, which is flattened, may be found a viscid mucous secretion. The remnant of the umbilical cord appears fresher looking than that of a child that has survived its birth a few hours."—(Herold's *Legal Medicine*.)

10. When abortion is undertaken by properly qualified physicians after due consultation with other physicians, and for the purpose of saving the life or health of the mother, it is *justifiable*; under all other circumstances it is *criminal*. The former is a perfectly lawful medical procedure; the latter is illegal.

11. A *dying declaration* is any statement made by a dying person who believes that he cannot recover and that he is, at that very time, in actual danger of death.

The statement need not be sworn to; it should be voluntary and sincere; and it is admissible as evidence in a court if the individual dies. An official or someone else should take down the deposition in the exact words of the patient, who should, if possible, sign the declaration.

12. "It has been shown to be most probable that the excess of sugar in the blood, upon which nearly all the symptoms of diabetes depend, is due to its over-production in the liver; and although it is tolerably certain that sugar may be derived from nitrogenous sources, we must admit that carbohydrate food constitutes its chief source of supply, and the one most readily controlled. It has therefore been established as the cardinal principle of the treatment of diabetes to restrict those articles of diet which have this chemical composition."—(Saundby.)

MATERIA MEDICA AND THERAPEUTICS.

1. **STRYCHNINE.** *Source:* *Strychnos nux vomica*, and *strychnos ignatia*. *Dose:* Strychnine sulphate, one-sixty-fourth of a grain; strychnine nitrate, one-sixty-fourth of a grain. *Action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension; it stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes.

2. "*Serum-therapy proper* is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are."

"*Bacterial Vaccines.* The term vaccine was originally applied to the infective virus or antigen of vaccinia (cowpox), but in modern usage has been extended to include the antigens of all infectious diseases. In the preparation of stock vaccines the pathogenic bacteria are grown in pure culture, then killed by heat, suspended with their toxin in sterile physiological salt solution, protected from contamination by an antiseptic, and standardized to contain a definite number of bacteria in each cubic centimeter. They are used by injection, subcutaneously or intravenously, to develop in the patient's body a condition of active immunity against the corresponding pathogenic germs or their toxins by raising the opsonic value of his blood and thereby promoting the phagocytosis of invading bacteria.

"The advantage of this active immunization for prophylactic purposes depends on the facts that these vaccines are incomparably cheaper and simpler to prepare than the sera, and that the active immunity conferred by them is more durable than the passive immunity produced by the latter. On the other hand their immunity does not set in immediately as is the case with the passive form, but only after 8 to 14 days of treatment."—(Potter's *Therapeutics and Materia Medica*.)

Three vaccines: Those for use against typhoid, bubonic plague, and cholera.

3. *Two heart stimulants that act quickly:* Alcohol and ammonia. *Alcohol* acts partly by reflex stimulation of the heart from irritation of the stomach, and also by direct action on the nervous and muscular mechanism of the heart. It should be given in small quantities (say half ounce of spiritus frumenti), slightly diluted, and as frequently as is necessary.

Ammonia acts by reflex stimulation of the heart and also of the vasomotor center in the medulla from irritation of the nose or stomach (according as the drug is inhaled or swallowed). Dose of aromatic spirit of ammonia, one dram in a little water. The effect does not last very long.

4. *For acute catarrhal dysentery:*

R.

Acidi sulphurici diluti, 3ss.

Tincturæ opii deodorati, 5j

Spiritus camphoræ, 3j.

Tincturæ capsici, 3ss.

Spiritus chloroformi, 3ss.

Spiritus vini gallici, 3jss. M.

Sig.—One teaspoonful, diluted, every three hours.

5. For incontinence of urine in an old person:

R.

Tincturæ belladonnæ, 5iv.

Potassii acetatis, 5j.

Aquæ menthæ piperitæ q. s. ad 5iv. M.

Sig.—One teaspoonful, diluted, t. i. d., between meals.

6. *Uses of potassium iodide*: "Its best effects are observed in *syphilis*; in the tertiary period it is more valuable than mercury, and in the late secondary period it is an excellent adjuvant. It should be given in ascending doses until improvement follows or symptoms of iodism appear. To secure permanent results, the treatment must be continued for six months or a year. In *parasyphilitic affections*—locomotor ataxia, parietic dementia, and arteriosclerosis—the iodide should always be tried, though, of course, no good can accrue from its use if there has been much destruction of tissue. Various opinions are held as to the value of potassium iodide in chronic interstitial inflammations, like *cirrhosis of the liver*, *chronic interstitial nephritis*, and *sclerosis of the spinal cord*, when a syphilitic origin can be excluded. Only small doses should be given, and these should be withdrawn on the slightest evidence of intolerance. In *subacute and chronic rheumatism* and in *chronic gout* it sometimes proves beneficial. It is believed that it aids in the absorption of the effusion in *serous pericarditis* and *pleurisy*. It is the most reliable remedy in *bronchial asthma* to prevent the return of the paroxysms. In *chronic bronchitis*, when the sputum is composed of thick, viscid mucus, it may be combined advantageously with expectorants. In doses of from 10-20 gr. thrice daily it is very beneficial in *aortic aneurysm*. In *angina pectoris* no remedy with the exception of the nitrites is so useful in preventing recurrence of the attacks. It should be given in daily doses of from 30-45 gr. for several months. In *chronic metallic poisoning*, especially from lead and mercury, potassium iodide is apparently efficacious. In large doses continued over long periods of time it has given very good results in many cases of *actinomycosis* in man."—(Stevens' *Modern Materia Medica*.)

7. *ASPIRIN*. *Origin*: From salicylic acid. *Dose*, five grains.

Physiological action: It is antipyretic, analgesic, sedative, circulatory, depressant, gastric irritant, and irritant to the kidneys. It may produce cardiac weakness, depression of respiratory and vasomotor centers, nausea, vomiting, dizziness, urticaria, and collapse.

8. *Salines* "act by stimulating the intestinal glands to increased secretion, and by their low diffusibility impede reabsorption, causing an accumulation of fluid in the intestinal tract which, partly from the effect of gravity and partly by gentle stimulation of peristalsis excited by distention, reaches the rectum and produces a copious evacuation."—(Potter.)

Three salines: Magnesium sulphate, potassium and sodium tartrate, and potassium bitartrate.

9. *Failure of respiration during ether anesthesia*: This condition calls for withdrawal of the ether; and if an inspiratory effort does not quickly follow, pressure should be made upon the front of the chest, and when this is relaxed a deep inspiration usually takes place, and no further difficulty is experienced. Failing this, the mouth should be opened and the tongue drawn forward with tongue forceps. Artificial respiration by Laborde's or Silvester's method should then be tried, and persevered in for at least half an hour. The hypodermic use of atropine, or strychnine is beneficial. Stretching of the sphincter ani and venesection of the internal jugular vein have proved serviceable. Tracheotomy may be necessary.

10. For *simple stomatitis*:

R. Thymol, gr. iv.

Glycerin, 5j.

Distilled water, 3i. M.

Sig.—Use as a mouthwash. Dilute if necessary.

11. *BELLADONNA AND ITS DERIVATIVES*. *Physiological effects*: Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

12. *Antidote of arsenic*, freshly prepared solution of ferric hydroxide; of mercury, milk or white of egg; of strychnine, chloroform, chloral, or tannic acid; of potassium cyanide, ferrous sulphate; of opium, potassium permanganate.

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS			
STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	Montgomery		
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix.	Phoenix	
Arkansas	T. J. Stout, Brinkley.	Little Rock	May 14
California	C. B. Pinkham, Sacramento.	Sacramento	
Colorado	David A. Strickler, Empire Building, Denver.	Denver	
Connecticut*	Chas. A. Tuttle, New Haven.	New Haven	July 9
Delaware	J. H. Wilson, Dover.	Wilmington	June 18

Cerebral Accidents in Tetanus.—Lumière and Astier first call attention to the well-known fact that as a rule tetanus spares the cerebral centers. The intellectual faculties are retained even in cephalic tetanus and by this test the latter may be distinguished from meningitis. During the present war, however, the authors have noted a type of tetanus in which the cerebral functions were disturbed even when prophylactic serum injections had been used. Febrile delirium and chloral intoxication could be excluded. The symptoms were of late supervention, from one to two weeks after the début of the malady, and persisted for at least one week. The type of tetanus was therefore subacute. The manifestations comprised hallucinations and phobias (fear of death in one case) which were of a fixed character. The termination in these cases is not mentioned.—*La Presse Médicale*.

WAR FOOD DIETING AND OUR PATIENTS.*

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

MUCH discussion has appeared of late in foreign medical journals regarding the effect upon civilian patients of the modifications in diet imposed upon them through necessities of the war, and the present time is appropriate to institute such discussion here. Moreover, physicians owe the patriotic duty of guiding patients in their endeavors to conform to the published war food regulations. In so far as war conditions may result in restrictions in quantity, *i.e.* in food deprivation, there is little that is new to be said—a starving man is a starving man, through whatever cause, and fortunately there is little real deprivation in this country. But where regulations concern substitute foods and abrupt changes in dietetic habits of long standing, although without restriction in total quantity of food, much ignorance prevails as to both aims and methods. For example, I know several instances in which a large retinue of domestic servants have gone on strike because of food restrictions suddenly and arbitrarily imposed by their employers, and in other cases, although the employer was observing rigid war food regulations, the fear of antagonizing and losing servants prevented securing their cooperation. Then there are the cases in which a too rigid adherence to a new dietetic regimen produces gastrointestinal disorder, changes in body weight, etc., which may prove a poor way of stimulating efficiency. In such situations the family physician can do much to promote the rule of reason.

The war food problem may briefly be summarized as follows (at least in so far as it concerns us at the moment): there are fully 10,000,000 Allies camping out (besides the others in reserve who are billeted) and we rapidly are adding 1,000,000 more men. A large proportion of these men (fully 60 per cent. in France, it is said) have been withdrawn from activities connected with food production, transportation, etc., and, of course, all the men must be fed exceptionally well to do exceptional work. Ten million men standing in rows near enough together to touch the outstretched hands would form a line extending three and a half times across the continent from Maine to California. These men who are camping out, *i.e.* living and

working in the open, in cold weather, need fully 4,000 calories per man per diem to accomplish efficient fighting. To this end they must have fat—fat for body fuel, fat for frying, fat for fighting foreign foes—for fat makes glycerin, glycerin makes nitroglycerin and other glycerin products, good for blowing up the Hun. Moreover, fats and oils are essential for lubrication of all kinds of machinery such as are used in transportation, in munitions manufacture, etc. Let us explain these simple equations to our patients and their cooks. The Germans estimate that the annual pre-war waste of fat found in the garbage pails of three families was equivalent to the fat of one pig. The Germans are feeling their fat shortage so keenly that they are recovering fats and oils from bones, from the stones of fruits, from sunflower and other seeds, and from traps set in sewage systems to regain laundry soap and other grease, even that derivable from feces. So much for the problem of fat saving, in order to maintain the fat content of the established army ration, which is 12 ounces of bacon per man per diem.

The second problem, that of wheat saving, is of equal importance, in order to maintain the army ration standard of 18 ounces of wheaten flour per man per diem, equivalent to a good-sized loaf of bread. Several persons have said to me, "We like wheat, why not send corn meal abroad, and let us eat the wheat?" Again the answer is simple and should be distinctly understood. Corn, as compared with wheat, does not keep or bear distant transportation nearly as well. It is liable to mold in ships' holds, to be eaten by weevils, or otherwise deteriorate. Corn meal bread crumbles readily and is far less easy to handle in army transportation than are wheaten loaves. Moreover, in France the baking of corn bread is not well understood or easy of accomplishment. In many small French villages home baking ovens do not exist, bread being baked in a community bakery. The French, not being accustomed to the use of corn meal, regard it as food fit only for hogs, recalling Dr. Johnson's famous definition of oatmeal, as "in England, food for horses; in Scotland, food for men."

One may not expect to change the dietetic habits of a nation in a few months. Were this country starving and should the Japanese offer to feed us almost exclusively upon rice, we should have a hard time of it. It is true that the American Army ration provides for the occasional use of corn meal, but only as a substitute, and not a constant component of the ration. Our normal

*Paper read before the Practitioners' Society of New York, March 1, 1918.

exportation of wheat to the Allies is 300 million bushels, but their deficit last year was much more than this, and we have now an "S O S" call from England alone for 75 million bushels in addition to all we have tried to send. The recent destruction of wheat through incendiarism and submarines is fearful to contemplate.

The problems of meat and sugar are complex, though less urgent, involving as they do, varied economic and transportation conditions, as well as the fact that one naturally tends to eat more of these foods in attempting to save fats and wheat.

In illustration of the importance of the use of intelligence in selecting food substitutes is the following incident: While traveling recently upon one of our trunk lines, in the dining car, a very obese man wedged himself in opposite me at the table. The menu card announced a "meatless Tuesday," but gave no hint as to how to select substitutes, nor were any special substitutes provided. So the fat man endeavored to nourish his 250 lbs. with a selection of macaroni, toast and other wheat foods, thereby eating much more wheat than he ordinarily might have done, thinking himself "patriotic." There is little gain in saving meat by wasting wheat. What he should have ordered, both for his patriotism and health, should have been fruit, an egg or two, and a salad with cheese.

The net results to be expected from prolonged "Hooverizing," in so far as they may be expected to produce nutritional changes, concern (1) variations in body weight, (2) modifications in digestion, and (3) changes in the stools. The normal, healthy person may make considerable change in long-standing habits of diet without noticeable effect, and often with apparent benefit, but with the invalid the resulting disturbance of function may prove disastrous, and it is poor economy in every sense to persevere with a regimen which lessens efficiency.

1. As to variations in weight, one meets with opposite conditions. There are those who have been heavy meat eaters, who may gain in weight through eating, instead, corn and oat products, even with less sugar and fat. In my experience, however, loss of weight is much more common, resulting from distaste for the coarser cereals, and a consequent net reduction in the total food intake. I have met with several instances in which from 15 to 20 lbs. have thus been lost within a period of a few months. Whether this be an advantage or not must depend naturally upon the individual case. With one or two persons I have had to insist upon a greater consumption of milk and cream, to raise the weight again to a standard more compatible with normal efficiency. In some cases a greater consumption of honey and maple sugar in lieu of cane sugar will maintain the body equilibrium.

2. The second group of cases are those in which careful dieting is essential through existing disease. A sufferer from chronic myocarditis with flatulent dyspepsia, being ardently patriotic, undertook to "Hooverize," mainly to set an example for her servants. The example which she set nearly cost her life, and I was obliged to insist upon complete absolution from her vows. There is another group of persons, of which we also see frequent examples,

namely, those whose starch digestion is persistently imperfect, if not impossible. When they try to eat "war bread" and "war cake," or the coarser cereals, such as rye and oatmeal, colic and all manner of digestive distress ensue.

3. In the third group of cases the modification in the character of the stools is due either to the use of various substitute fat foods, or the accumulation of the coarser cereals. In these cases it is the colon which must be reckoned with. A patient who had thus dieted himself for some time voided feces of inordinate bulk and length. Finally the accumulation resulted in impaction with fever and intense colic which at one time gave rise to the suspicion of a perforated appendix.

The aged, as is well known, frequently are intolerant of the coarser cereals, as, in fact, they are of any radical dietetic change, and here again absolution should be granted.

Fortunately all these common evils are easily preventable, and my purpose in directing attention to them anew is to emphasize the importance for the physician to supervise and direct with special care the diet of patients, whether specifically consulted about it or not, and while most earnestly urging the imperative necessity of food conservation in increasing degree, to see to it that its simple problems are understood and intelligently met.

61 WEST FORTY-NINTH STREET.

SOME MANIFESTATIONS OF THE PARENT COMPLEX.

BY ADOLPH STERN, M.D.,

NEW YORK.

UNFORTUNATELY, many have come to look, erroneously, upon the parent complex as indicative of a state of affairs somewhat as follows: A more or less conscious incestuous fixation or desire on the part of an individual for the parent of the opposite sex, with a conscious feeling of hostility for the parent of the same sex. While, if conceived of as a process totally unconscious to the individual, this does represent the essentials of the complex, yet the manifestations of its presence are so manifold that I wish to present some of those more prevalent and at the same time more easily discernible and comprehensible.

In this contribution I shall emphasize the physiology and the pathology of the parent complex, showing that its existence at a certain period is essential for the individual's emotional or affective growth, especially in the field of love. Secondly, as I said above, I shall describe some of its important manifestations, and, thirdly, I shall suggest some measures which, put into use during the child's early life, shall tend toward preventing a purely physiological process from developing into a pathological one.

The typical parent complex phenomenon, with its essential components, is pictured in the following incident: A healthy, lovable, good natured little fellow, of four years of age, normal in every way, said, in the presence of both of his parents, "Father, I'm going to kill you and marry mother." The little boy instinctively chooses his mother, the

opposite sex, and at the same time effectively demonstrates that his marriage to his mother necessitates in some way the removal of his father, the surest method being, in the child's mind, killing.¹

This should give rise to no misconception. As one might be led to infer, instead of an enmity (conscious) existing on the part of the child for his father, in reality, the little fellow loves and idolizes him, and the two are very close chums.

This picture is one that commonly presents itself in one form or another in the life of most, if not all, children. It represents a physiological attempt on the part of the little fellow to do what his father did, namely, to get a wife. One may conceive of the boy's impulse to "kill" his rival the crude, instinctive manifestation of the later sublimated impulse of the adult to achieve success in love (choosing a mate) by the exhibition of qualities superior to those of his rivals.

The choice of the mother as his mate denotes the instinctive sex selection. The picture given above, with the modifications pointed out in note 1, is identical with the adult's conception of what constitutes mating—exclusive sexual possession.

That is what the child learns and naturally so. Surely no better model as a wife can exist for a child than his mother, for she to him is an idealization of all that is desirable.² So that in addition to the general culture, breeding, and knowledge which a child gets from the parent, more important perhaps than all this for its happiness, the child learns from its parents how to love. There is nothing "wrong" in the child's loving its parents, in his infantile way. He is but preparing himself for the future. In this process we see a normal physiological phenomenon in the individual's culture development.

The pathological aspect of this phenomenon I shall now attempt to make clear, seeking at the same time to bring to light those (or at least some of those) factors concerned in the pathogenicity of an otherwise normal process of growth.

That parents should play a very important rôle in the lives of their children is to be expected. Boys and girls, when they mature, often seek as their mates those, in the case of the boys, resembling their mother or a sister, and the girls those individuals resembling their father or a brother (the sister or brother being taken as a youthful reproduction of the parent).

Up to a degree, this is as it should be. In those instances where the mother serves her purpose as a model after which the boy patterns his love object, and the model ceases to exist as an object of desire after the (strange) love object has been found; in such an instance we say that the parent complex has served its purpose. The child has learned to love, in his infantile way, and as he matures transfers his desires (now also matured and different from the infantile) to a stranger, in the process destroying the model of the parent, as a love object, since its purpose, as such, has been fulfilled.

We should regard love as an instinctive, essentially pleasure impulse, characterized in animals by the reproductive act. Among them no laws exist prohibiting the mating of blood relatives. The animal follows its own desires, their fulfillment being

dependent on physical limitations. The child, too, is essentially instinctive in its wants. It as yet knows no laws, except that of physical limitations. As the child grows it learns that not only physical limitation, but morality also, and in an increasing measure, sets limits to the fulfilment of desire. We know that our cultural development depends for its progress on the rejection or, better, sublimation of many of our primitive (pleasure) impulses.

By means of this apparent digression, I wish to point out the pathological nature of the parent complex in the neurotic. We say that he has failed to make use of that phenomenon to help him along: with him it is not a means to an end, but an end in itself. He is fixed on the road of his emotional life. To him the parent is not a model, but an object of desire, just as in the case of the child³ and, important to note, in the same way. This gives rise to the fact that the neurotic in his emotional life is characteristically infantile. In this very important phase of his life, without his being consciously aware of it, he lives in the past, unable as an adult to transfer this love to a stranger and thus unable to have his emotional life keep pace with his intellectual progress.

In individuals in whom the parent complex has not served a physiological purpose there are present evidences of this maldevelopment. Some of these individuals are neurotics; others are apparently normal. These latter are such as are able to maintain a more or less satisfactory emotional life, in spite of the unconscious conflicts present. In both classes, on analysis, evidences of this pathological emotional development are manifest, chiefly by the infantile (undeveloped) state of the sex life.⁴ These I shall now describe.

Such individuals as I have indicated, among other characteristics, show wide, rapid, easily produced fluctuations of depression and elation. They suffer often sexually, either from impotence or premature ejaculation; and very often, in my experience, are subjects of sexual hyperesthesia, indulging frequently in intercourse, the act being preceded by such an intense anticipation that the act itself does not fulfill that expectation, urging the individual on to repeated acts, yet leaving a constant "sexual hunger." The type of individual just described, in spite of repeated indulgence in intercourse, has numerous, vivid, emotionally colored fancies of an amorous nature. These fancies occur not only before the act, but very often immediately following it, the act itself not quieting the sexual desire.

Many of those unable to sublimate the parent complex, especially those who have indulged in intercourse either infrequently or not at all, conceive of a woman as a superior being, a goddess to be worshipped from afar. They put her on a pedestal, as if she were made of a substance different from that which enters into the composition of other beings.⁵

In those still laboring under the inhibiting influence of the (non-sublimated) parent complex another characteristic manifests itself, both in men and women, in their marrying late in life. Many such women are of a "retiring" nature or disposition, thus being inaccessible to men; or some of the women being unable to find the "suitable" man.

Among the men many reasons are given, the chief one being financial; they say they are unable to support a home. Some feel an uncertainty to remain true to any one woman for any length of time. This last reason is one frequently given by patients.

While such are the reasons given, yet on investigation they prove to be what Jones has termed "rationalization," or the necessity of the individual to find a reason or explanation for every phenomenon. In reality, at least in those under my direct observation, the basic (unconscious) reason for the late marriage was the inability of the individual to break away from the old ties and find a new home for himself (or herself).⁶

Among women sexual impotence (sexual anesthesia) is a very common symptom, and at least one of its important causes is the inhibiting effect of the repressed parent complex. Many women show so strong an attachment to their father that they enter the bonds of marriage with reluctance, with a sense of duty rather than a feeling of love. Such women, try as they will, cannot experience sex feeling during the sexual act. While such women are, as far as in their power lies, devoted wives, yet their frigidity is a sign of the incompleteness of their love. For love, no matter how ideal, shows its consummation in the sexual act, which is incomplete if the orgasm is lacking. These women often have a variety of subjective complaints—pains, dizziness, paresthesias, headaches, etc. In this symptomatic way, they proclaim that they ail—and they do ail on account of their inability to satisfy a normal desire, even though they indulge frequently in intercourse. Many such women masturbate after the act, in order to produce an orgasm, showing thereby the infantile or undeveloped nature of their sex impulse.

Masturbation or, at least, its persistence into adult life may more or less directly be traceable to the parent fixation. A striking illustration came under my observation about one year ago. A young man of twenty consulted me for apparently causeless periods of depression, irritability, and restlessness, usually of short duration. It developed that these periods usually followed his acts of masturbation, and that, in part at least, it was the cause of the masturbation that was responsible for the depression. The patient was in the habit, at the time he came to me, of listening for any sound from his parents' room indicative of the sexual act; also he was in the habit of looking through the keyhole of the bathroom when his mother or any of his sisters was bathing; or if he knew that any female member of his family was in the bathroom he pictured to himself their naked forms. All these incidents and fancies were provocative of sex excitement, culminating in the act of masturbation. The patient felt intense remorse after each act of masturbation. I feel that the degree of remorse was determined by the content of the fancies, *i.e.* the more or less conscious realization of the guilt of an individual who, directly or indirectly, takes a member of his family as his sexual object.

I have purposely mentioned some of the more evident manifestations of the parent complex as they exist in many apparently normal individuals, and also in neurotics, because they are very preva-

lent and because the measures I shall suggest, not for their cure, but for their prevention, are more applicable to these manifestations than to those more complex and symbolic ones (symptoms) which we see in the neuroses themselves.

Since the parent complex is a physiological state at one stage of the individual's development, what factors convert it into a pathogenic condition? Why in one individual does it persist later into life than in another? These questions are more easily asked than answered. Yet I feel that a great deal of light has been thrown on them and that we are in a position both to explain the persistence of this phenomenon, and at the same time to formulate some measures which, put into use in the bringing up of children, will tend to a great extent to diminish the harmful effect of the persistence of the parent complex and bring about a more nearly parallel growth in the emotional and the intellectual spheres of the individual.

The general impression seems to prevail that neuroses are the result of traumata, especially sexual, which the child receives early in life. If this were the case, neuroses, common as they are, would be still more prevalent, for many more are exposed to these experiences than develop neuroses. Such an assumption does not take into consideration the individual himself. Freud recognized this, and has called attention to it. What I believe, however, has not been sufficiently brought out, is the direct influence the immediate early environment has upon the individual. I mean the environmental influence before the child has reached the age of five. These influences exert their forces so early in life that we are very apt to talk of the characteristics manifested by very young children as being inherited. An inherited quality or characteristic is contained in the germ cell, transmitted at the time of impregnation. Neurotic characteristics, I believe, are not inherited, as we can very readily conceive of them as acquired characteristics. These, as we know, are not hereditary. A conception of the neurotic constitution as representing a retarded emotional development will enable us to clear up many things heretofore in the dark. We say that a child is born endowed with instinctive impulses, on the renunciation or sublimation of which, as it grows older, depends its moral or ethical development. How will it do this best? Given an environment which prevents the sublimation of these impulses, maldevelopment results. This conception throws the blame for the neuroses on the parents. Not that the children inherit neuroses from them, but owing to some neurotic or abnormal trait in the parent, a normal development of the child is not as likely to result as when normal conditions exist. So that given an individual in such an environment, in addition exposed to sexual or marked emotional trauma, we say that such an individual is predisposed to the development of a neurosis. He has been retarded in his emotional development. He will react, even to the ordinary influences of life, in a way different to the reaction of one not so predisposed. With this digression we are ready to take up some of the more important parental shortcomings that will tend to prevent in a child a proper sublimation of an otherwise physiological phenomenon, namely, the parent complex.

Among neurotics "favorite" and "only" children form a very large group. These are children who receive too much attention and love, and who later in life expect society in general to take towards them the same attitude that the indulgent parents did. Such individuals look upon those people with whom they come in contact, as "parents" and expect from them what their own parents had given them. Yet the blame for this condition, which is one of the most important predisposing causes of a neurosis, lies not with the patient, but with the parent, who fostered in the child a craving it never learned to renounce.

Parents who choose favorites among their children, do so, in my opinion because they see in that favorite child some quality, physical or psychic, for which they had looked in vain or no longer see in their marriage partner; and having found it, shower upon that child all the love and devotion that should normally go to the wife or husband, as the case may be. This is but another way of expressing the disillusion of or dissatisfaction with the marriage and an attempt to satisfy the desire through the unconscious replacement of the marriage partner by one of the children. It is a most common phenomenon that the mother's favorite is a boy, and the father's choice is a girl. In this also, we see an unconscious sex selection, beginning on the part of the parent and later becoming reciprocal.

How often we hear parents, especially mothers, say, "I do not like to see my child grow up. I want to see it remain a child." Such children as a rule are mothered too much, over sheltered and protected, fondled and cuddled to a pathological degree, and have engendered in them desires and longings which only the parents satisfy. Such children "cling" to the parent and later hesitate to venture into matrimony: firstly, they fear they cannot readily get that to which they have been accustomed, and secondly, they have not been prepared to lead an independent existence. They have not grown up, and are unfitted for the life of a normal adult. Such a child is frequently kept by the parent in close contact to the latter, the two at times sleeping in the same room or even in the same bed; the child is dressed, bathed, and washed, by the mother up to an age when it should look out for itself in these respects at least. There is no doubt the mother derives a great deal of pleasure from all this. What the nature of this emotion is, one cannot always say. However, the child, too, receives pleasure from this contact, and in those patients who have gone through some such bringing up and have been analyzed, the nature of this pleasure has been ascertained to have been of a distinctly sexual nature.

Something to which Freud has called attention and upon which he lays great emphasis as important factors in the production of the neuroses, is the general attitude toward things sexual and the inability of parents to explain to children the nature of the sexual act, of conception and child-birth as they take place in the adult human being. These are all of vital interest to the child. They are subjects to which the child gives much time and thought, as manifest in its questions and games. The evil influence of this lack of knowledge is made possible because children have such (to us, but not

to them) queer conceptions of these matters, and because these conceptions persist, as working bases, with the neurotic and also with normals, into adult life, making it impossible for the individual so handicapped to take towards the opposite sex the normal grown up attitude in respect to love. That is one of the reasons for Freud's statement that a neurotic cannot love. He cannot because, unconsciously it is true, his (or her) sex life is still in the infantile state: a condition unsatisfactory to an adult individual and fraught with danger to his or her emotional life.

In conclusion, I wish to summarize:

1. The parent complex is a physiological phenomenon, quite essential for every individual at a certain stage of his development, pathological only when it persists into adult life; in which case so to speak, it is an end in itself, instead of a means to an end.

2. It manifests itself in various ways, all of them unconscious to the individual, yet potent in its possibilities for harm in his life.

3. The responsibility of the parents in the persistence of the parent complex and incidentally in the production of neuroses. I emphasize the part played by the parent, for to my mind, it explains the influence of heredity, so called.

NOTES.

1. If as Freud has pointed out, we regard the concept "death" as it exists for this child as a "going away," we can readily understand why children so often use this method of ridding themselves of all undesirable competitors. The little fellow made the statement in a perfectly unconcerned, matter of fact way, with no emotional display of any kind. The child did not hesitate to tell his parents what he intended to do to accomplish his ends. As yet, in him, the wish is not repressed. The moral sense does not as yet act as a repressing agent, for no moral sense exists. This conscious, non-repressed wish of the child is the unconscious repressed wish of the adult neurotic, and lies at the base of the functional neuroses as the prime etiological factor.

2. It is my opinion that those individuals who carry with them unconsciously, it is true, a picture of their parents, purely emotionally colored, and seek their mates based on these memories, often realize a disappointment in their married lives. For no mortal can rise to the level of an ideal, purely emotionally conceived, an ideal in which reason or judgment does not see the human faults and weaknesses present in all beings. Such seekers see their idols (or ideals) crumble when the latter manifest their human side.

3. Unless we bear in mind that I always refer to these desires as unconscious ones we shall be led to reject offhand that to which we otherwise would give serious consideration. The neurotic also rejects the suggestion that one of his parents is to him an object of desire. For to him, as to all of us, the thought of a state of affairs such as I have described being a consciously desired one, is repugnant, not in accord with his otherwise normal development; and it is this disharmony between desire and repression which gives rise to a conflict, at the same time submerging that desire into the unconscious. Here it remains as a wish, still active and potent, making itself manifest in various ways, some of which I shall illustrate.

4. These defects are present also in other spheres than the sexual only. However, I have chosen the latter as the more accessible to the physician.

5. How like the concept of the parent image to the child, and yet how, for the adult, a very unreal picture. The same holds true of those women whose concept of "man" is so impractically idealistic.

6. Freud has indeed well said that very often a conscious "cannot" should be interpreted as an unconscious "do not wish to." So, in the illustration, we

say that such individuals do not wish to break their old home ties to form new ones. Some of my patients thus constituted, even after their marriage, made their home with the parents or parents-in-law, giving various reasons for so doing. Yet either during, or immediately after analysis, without any change taking place in the conditions which had determined the establishment of the joint home, they readily founded a home for themselves.

7. On several occasions mothers of little boy patients have told me that the latter had manifested an erection of the penis when the hand of the mother, in the process of bathing her child, came in contact with its genitals. The mother of a little girl informed me that the child in the process of being bathed would hold for a moment the mother's hand between its thighs when the hand came in contact with the little girl's genitals.

8. For a long time I doubted the wisdom of describing the sexual act to children. My hesitation was due to my own (false) modesty. My little patients often asked me, "Where do children come from?" I told them in an illustrative way, citing the process in plant and then animal life. This, however, I learned by experience proved to be of very little actual value, for children take things very literally and they repeated the question after my explanations. Many children, whose parents or teachers attempted to answer the question as I had done, repeated the question on several occasions, showing that their curiosity or desire for knowledge in that quarter had not been satisfied. As time went on, I, too, felt that while what I had told the children was correct enough, it did not give to the child that concrete knowledge which is essential for its understanding of the process. While descriptions of plant fertilization and growth are no doubt of educational value, they cannot serve as an answer to the child's question "where do babies come from?" Nor can these descriptions be used as stepping stones to knowledge which is to serve as an explanation. You cannot "lead up" to an answer. The child who asks that question needs a definite, concrete, accurate answer. For he or she has heard or seen something the nature of which is not clear. We cannot expect the child to be able to draw a parallel between the processes in plant and animal life, and apply it to human beings. That serves its purpose in a course of biology later in life, but does not answer the question of the child. Nor can the answer safely be postponed. It should be given at once. Every child, no matter how young, who asks the question, is able to understand the correct answer.

40 WEST 84TH STREET.

FRACTURE-DISLOCATION OF THE SACRUM; RUPTURE OF THE THIRD, FOURTH, AND FIFTH LEFT SACRAL ROOTS, AND COMPRESSION OF THE SAME ROOTS ON THE RIGHT, AND ALSO OF THE SECOND SACRAL ROOT ON BOTH SIDES; WITH SOME OBSERVA- TIONS ON SUPERFICIAL AND DEEP INNERVATION.

BY JOSEPH BYRNE, M.D.,

NEW YORK.

ATTENDING NEUROLOGIST, CENTRAL NEUROLOGICAL HOSPITAL;
CONSULTING NEUROLOGIST, FORDHAM HOSPITAL;

AND

ANTHONY H. HARRIGAN, M.D.,

NEW YORK.

ASSOCIATE VISITING SURGEON (ACTING), FORDHAM HOSPITAL.

The following is the history of the patient:

W. C., 44 years of age, carpenter, on Jan. 17, 1917, fell from a scaffolding a distance of nine feet, the sacrum striking on a beam; from this falling again to the ground, a distance of six feet. Immediately after the injury the patient was unable to walk; had voluntary motion but no control of legs. For two weeks following catheterization was necessary. Ever since the injury he has had loss of control of bladder and rectum,

with absence of erections and of sexual desire. He does not know when he wants to pass urine or feces. The bowels do not move without a purgative. He experiences, when the bowels move, a severe gripping pain in the abdomen; is not conscious of bowel movements. Bladder control is also defective, the patient not knowing when he wants to void. After the bladder has been emptied by a catheter it takes three or more hours before the patient begins to have a "feeling" in his bladder. By straining the abdominal muscles he can force out a small amount of urine in a steady stream for a short time. In general, when the bladder is full the urine comes away in little gushes at intervals of several minutes. Sexual desire and efficiency have been markedly impaired since the injury. No erections at all for some time past. These defects in the rectal, vesical, and genital mechanisms constitute the chief complaints. Patient had to wear a urinal and diapers. He was a strong, muscular individual. Examination on Aug. 18, 1917, showed that there is a bulging and deformity of the sacrum; marked kyphotic deformity with slight scoliosis to the right at the base of the sacrum; depression at lower end of spine on left into which could fit a hen's egg; to the right of this was a piece of loose bone, proved by rectal examination to be the dislocated coccyx. This was attached to the right pelvic bones by muscle and ligament. It was free on the left.

Patient was examined by Dr. Byrne, whose diagnosis was: Fracture and dislocation of the sacrum with rupture of the second, third and fourth sacral nerves on the left side, with contusion and stretching (partial obstruction) of the corresponding roots on the right, and of the second sacral roots on both sides; fracture and dislocation of the coccyx. Operation was advised.

X-ray examination (Aug. 20, 1917) of the lumbar spine shows nothing definitely abnormal, except that the fifth lumbar is apparently lower than normal, and overlaps the sacrum more than is normal, the lower border of the transverse processes being slightly lower than the internal masses of the sacrum.

Most of the pelvic portion of the sacrum, however, shows very definitely abnormality in the way of loss of bone substance and general appearance of disintegration, leaving only a small amount of the left border displaced slightly to the left. On the right side there is somewhat less bone disintegration, and the coccyx seems displaced about 2 inches to the right and about 1 inch higher than normal. The apparent loss of bone substance, estimated 3 x 3 inches, may be due to the absorption of bone and lime salts after a comminuted fracture; absorption of bone after sarcoma; possible absorption from necrosis and osteitis.

As the damage to the pelvic portion of the sacrum is extensive the interference with the function of the sacroplexus, caudaequina, and nerves should be considerable. Supplementary x-ray examination of the lumbosacral region, stereoscopically, shows no conclusive evidence that the fifth lumbar is displaced forward on the sacrum. The case seems to be one where the angle between the lumbar and sacral regions is much increased, until the upper and articular surface of the sacrum faces forward more than usual, carrying with it the fifth lumbar vertebra until the anteroposterior view shows the fifth lumbar vertebra and its transverse processes to be much lower than usual in their relations with the upper border of the sacrum. The total destruction of the lower half of the sacrum is confirmed, as detailed in the first report.

Motor system: No appreciable defect except the vesical, rectal, and sexual disturbances already described.

Sensory system: Spontaneous phenomena: Numbness over both buttocks; at times a "feeling" shoots from the anus to the penis; sensation of pressure and discomfort in the hypogastric region, at times (with full bladder) after lying on his back for some time a feeling of soreness is experienced in the right buttock. No other pain or tenderness.

Elicited phenomena: Upon light touch for the finer von Frey hairs, the parts having been shaved, sensibility was lost as represented in Chart 1.

Tests for the compass, points simultaneously applied, showed over the anesthetic area on the buttocks (SIII) marked impairment when moderately firm pressure was used, less impairment where more pressure was

made and perfect answers when the pressure was still greater, though short of causing pain. Thus on the left buttock, the points being $3\frac{3}{4}$ inches apart with moderate pressure, the answers in ten trials were with "ones," ten right and none wrong; and for "twos" ten wrong and none right. For deeper pressure at $3\frac{3}{4}$ inches the answers were for "ones" ten right and none wrong, and for "twos" seven right and three wrong. For still deeper pressure the answers for "ones" and "twos" were perfect.

over both buttocks (SIII) the answering was excellent, the threshold being reasonably low. With the points 2 inches apart the answers were perfect.

Prick: For the algometer at two grammes pressure, sensibility was lost on the left side over an area somewhat less in extent than the loss for light touch. On the right the loss was less extensive (SII). Marked overreaction was encountered on the left buttock when the boundary of preserved sensibility was reached by the pin-point dragged from the analgesic area outwards.

FIG. 1.—Showing light touch loss for the finer von Frey hairs in rupture of the third, fourth, and fifth sacral roots on the left, and contusion, stretching, etc., of the same roots on the right, and also of the second sacral roots of both sides. A small area of preserved sensibility at the junction of the scrotum and the thigh is not shown.

Pressure touch: For the unweighted esthesiometer sensibility was absent on the left buttock to an extent slightly less than the loss for light touch. On the right buttock the loss was considerably less in extent than on the left. For heavy pressure sensibility was preserved all over both buttocks and localization for touch, when felt, was good.

Compasses: For two points *consecutively* applied

On the right side the overreaction was not so marked or so constant. On the glans penis prick sensation at twelve grammes pressure was absent on both sides for single stimuli. Where the stimulus was rapidly repeated some sensation of pain could be evoked on the right side, even at a pressure of three grammes. The same was true for the scrotum on both sides, especially that portion bordering on the thigh (ilioinguinal nerve).

Pinching: Superficial pinching, no matter how severe, did not cause pain on the left buttock (SIII). When, however, the fold of the skin grasped between the nails of the thumb and finger was so large that the skin folded then pain was felt at the site of pinching.

Pressure pain: The average threshold was found to be at nine kilos, on the centre of the left buttock and six kilos on the right. Localization was good, wherever pain was evoked by pinching or pressure, and when the threshold in each case was reached, the impulses into consciousness were gradual and without overreaction. Reflected and referred pains were looked for but no areas could be worked out at this examination.

Examinations on Sept. 10 and 12 showed the cutaneous hyper-algesia that accompanies reflected pain on the areas depicted in Fig. 1 (SIII). The patient suffered from a slight stricture of the posterior urethra so that it was found difficult to pass a No. 16 F. catheter. The

hyperalgesia sensibility for light touch, compasses simultaneously applied, prick at two grammes, single stimuli, and intermediate degree of heat and cold were markedly impaired especially on the areas below the gluteal folds, the impairment being more marked on the right side.

Temperature: For intermediate degrees of heat (38° — 40° C.) and cold (23° — 25° C.), the area of lost sensibility corresponded closely with that for light touch (SI). For gross heat (55° C.) and cold (ice) the loss for momentary light application corresponded closely with the loss for prick at two grammes pressure (SII). Extreme heat (70° C.), when lightly and momentarily applied to the buttock, showed no sensation, but when the application was made with some pressure for a longer time, pain was felt and the patient was able to recognize the stimulus as hot. The sensation was not accompanied by overreaction. Experience and

FIG. 2.—The heavily dotted line bounds the area of absolute loss for the lighter von Frey hairs; and for intermediate degrees of heat and cold. Dots and dashes bound the area of loss for prick at two grams pressure and for gross heat and cold on that superficial contact. The central drawing shows the areas (unshaved) of preserved sensibility on the scrotum.

urethra was forcibly distended by injection of sterilized olive oil, when the catheter was readily passed. Examination before this procedure, when the patient was not in pain from bladder distention, showed no hyperalgesic areas except that immediately bounding the anesthetic area. After passing the catheter the cutaneous hyperalgesia appeared. This was most pronounced at the boundary of the area shown on and about the buttock in Fig. 1, outside of the anesthetic areas on the perineum, inner thigh, scrotum, and penis. A lesser degree of hyperalgesia was found on the upper thighs, veins, and lower abdomen. Careful tests showed that a still lesser degree of hyperalgesia could be marked out for each and every important nerve of the sciatic distribution in the legs. Here undoubtedly the phenomena were of the "referred," as opposed to the purely "reflected" variety. A noteworthy feature was that after the development of the reflected cutaneous

care are necessary in making this test, otherwise the skin may be injured. Ice when massively applied with some pressure did not so readily evoke the specific sensation of cold.

Reflexes: The bulbocavernosus reflex was absent on both sides. The anal reflex could not be elicited when the skin or mucocutaneous area was touched, stroked, or pricked, cephalad of the center of the anus, but could be readily elicited caudad of this level. It could also be elicited by stroking the buttock laterad of the boundary of light touch loss or by deep pressure (touch or pain) over the center of the buttock.

Discussion of the Symptoms and Signs.—The following points are of interest: The lowermost motor portion of the reflex mechanisms (efferent arcs) controlling the neck of the bladder and the anus,

though functioning irregularly, were manifestly intact. Compare the constipation and the urinary retention on the one hand, and the incontinence of urine and feces on the other. The nerve supply of the bladder wall comes from the cord through the second, third, and fourth lumbar (vesical plexus), whereas that for the neck of the bladder comes through the second, third and fourth sacral roots (hypogastric plexus, *nervi erigentes*). The retention, therefore, of motor and sensory function (hypogastric pain) in the bladder wall is readily understood. The sphincters of the bladder and rectum, when cut off from their spinal nerve supply, assume a state of postural hypertonus (Sherrington, Elliot) which accounts for the urinary

The elicited phenomena showed absolute loss for touch, pain, and temperature on the left side on an area corresponding to the third and fourth sacral root distribution, so long as the stimuli involved only the superficial structures. When the stimuli were so applied as to reach the deeper structures, just under the skin, then sensibility for touch, pain, and temperature was preserved. This seems to show that nerves running in the subcutaneous tissues (aponeurosis, fascia, synovial sheaths and coverings of tendons, *et cetera*) have specific receptors independent of those situated in the skin proper and have a level of entry into the cord different from that of the nerves supplying the superjacent skin. This fact was further demonstrated by one

FIG. 3.—Showing reflected pain areas, cutaneous hyperalgesia from bladder and urethral irritation.

retention, constipation, and loss of all admonitory sensations such as accompany a full bladder or rectum. However, when once the sphincteric hypertonus is overcome mechanically or by inhibition through local mechanisms, then the sphincteric muscles again assume a state of postural tonus in the lengthened state (Sherrington) which, for the time being, permits of incontinence of both urine and feces. These conditions of postural tonus in muscles innervated by the sympathetic or autonomic system, are effected through local mechanisms. Compare the paradoxical pupil dilatation and paradoxical vascular constriction (ear vessels) after removal of the superior cervical ganglion.

of us in tests made directly upon these structures in large open wounds, and in the present case by the use of needles and of hot and cold solutions injected into the structures beneath the insensitive skin. It seems therefore that Head's well-known division of the peripheral system of nerves into three sets of fibers, viz., epicritic, protopathic, and deep is inadequate. Sherrington's division into the exteroceptive, proprioceptive, and enteroceptive systems seems more logical but requires qualification. For clinical purposes the most serviceable division of the peripheral system would be into

(a) Superficial critical, corresponding to Head's epicritic, including light touch and its localization.

compass points lightly and simultaneously applied; degrees of heat and cold around the neutral points, *i.e.* the skin temperature.

(b) Deep critical, including pressure touch and its localization, compass points consecutively and simultaneously applied with firm pressure; posture and passive movement; specific sensation of sharpness and its localization, and of gross heat and cold; certain elements in vibration and roughness; size, shape, form, consistency, and weight on the supported hand, *et cetera*.

(c) Superficial effective, including pain or hurt from light stroking of the skin or hair; superficial pricking and pinching; from the superficial momentary application of extremes of heat and cold; or the pleasurable excitement of light contact with smooth objects, or soft fur, warm objects, *et cetera*.

(d) Deep effective, including pain or hurt from deep pricking and pressure; from prolonged application of gross heat or cold; from vibration or roughness, or the pleasurable sensation from massive prolonged application of moderate degrees of heat or from mild vibration or moderate degrees of roughness, *et cetera*.

The absence of pain and tenderness in the totally denervated skin areas on the left buttock and the presence of them on the right, with some evidence of regeneration or restoration of function on the latter region—these facts are important, since at operation it was found that the third and fourth sacral roots were completely destroyed on the left, whereas on the right they were intact but slightly stretched and imbedded in connective tissue. These observations confirm the experience of neurological surgeons who find that section of the posterior nerve roots or of the pain paths in the cord completely and permanently abolishes pain and tenderness in related areas at the periphery. Further corroboration is found in the usually painless course of syringomyelia, and in tumors of the spinal cord (Elsberg) as long as the posterior nerve roots are not compressed (partially obstructed). From these and other facts it may be concluded that the fundamental dynamic factor in all conditions of pain and tenderness is to be sought in processes taking place chiefly in the cells of the dorsal root ganglia, as one of us (Byrne) some time ago pointed out in reference to the pain crises of tubes.

Operation by A. H. Harrington, June 22, 1917.—Ether narcosis; prone position; iodine preparation. An incision seven inches long was made over the center of the sacrum. This incision was extended above over the lumbar spine and prolonged below to the coccyx. Exposure of the bone revealed definite bending or kyphosis in the upper part of the sacrum. There was a dislocation of the sacrum at the right sacroiliac synchondrosis. This dislocation caused the posterior surface of the sacrum to occupy an inclined plane, which inclination, coupled with the fracture deformity, made it difficult to recognize the normal contour of the bone. With the use of chisel, gouge, and trephine the central canal of the sacrum was opened, the cauda equina, which was found lying in the central canal, appearing as a thin bluish structure. In order to establish its identity which was partly in doubt, a part of the laminae and spine of the last lumbar vertebra was removed, definitely establishing the structure previously noted as the cauda equina, by its passage upwards into the central canal of the lumbar vertebra. At the point where the cauda equina entered the sacral canal it had suffered a displacement or pushing backwards so that, at this point, its direction was almost at a right angle to that

which lay within the lumbar vertebrae. This curving or bending backwards of the cauda equina was caused by the posterior displacement and fracture of the sacral vertebrae. Investigation showed that the cauda equina was completely immersed in scar tissue; this scar tissue was carefully dissected away so that the cauda equina was completely freed. Examination demonstrated a rupture of the third, fourth, and fifth sacral nerves of the left side, confirming Dr. Byrne's diagnosis. The distance between the ends of these nerves and the cauda equina following complete freshening of the ends with a sharp scalpel measured from one-half to three-quarters of an inch. Each nerve was sutured to the central cauda equina with a mattress suture of plain catgut—"suture à distance." The coccyx, completely dislocated from the sacrum, was removed. Further exploration showed that a large plate of bone had been detached from the anterior surface of the sacrum and was pressing firmly against the pyriformis muscle. Between this bone and the sacrum an adventitious bursa had developed. The bursa was dissected away and the flake of bone removed piece-meal. This proved to be the most laborious and difficult part of the operation. An attempt was made to transplant a piece of fatty tissue into the space lying above the sutured nerves. This was given up, as no suitable tissue could be found. The overlying muscles were sutured with catgut; a small drain was placed in the lower angle of the wound, and the wound was closed with interrupted sutures of silkworm gut. The drain was removed at the end of forty-eight hours; the sutures were removed at the end of seven days, primary union.

Repeated examinations since the operation has shown some improvement in the sensory mechanisms supplying the scrotum, penis, perineum, and right buttock. The sensory condition over the left buttock (third and fourth sacral root area) shows no return of sensibility as yet. The vesical, rectal, and genital functions show some improvement. Though there is serious doubt as to whether regeneration will take place in the sutured nerve roots on the left side, the relief of the partially damaged roots (sacral third, fourth, and fifth) on the right side may prove sufficient to secure some restoration of the preganglionic fibers supplying sphincteric function. Elliott has shown that after unilateral destruction of the bladder, restoration of function occurred with uniform well-coordinated contraction, as the result of preganglionic neurones on the sound side extending to and establishing connections with the decentralized local mechanisms. Compare the normal functioning of the heart after section of one vague nerve.

Researches in Variola-Vaccinia.—Gauducheau has studied cowpox immunization in the Tonkin Institute for the past 12 years and announces that there is no absolute differentiation possible between these affections and that either immunizes against the other. Mutation of variola to vaccinia has been partially successful. The differences are due only to the adaptation of a common virus to two animal genera—men and bovidæ.—*Bulletin de la Société de Pathologie Exotique.*

SURGICAL ANOMALIES OF THE ILEOCOLON.

BY HOWARD BARBER, M.D.,

NEW YORK.

(From the Department of Surgery, New York University, and Bellevue Hospital Medical College.)

THE digestive organs in youth resemble those of the carnivora and in the later years those of the herbivora. The relative predominance of these characters has been emphasized particularly by Ricketts, Bryant, and others. The lower right quadrant has long been of especial interest in this regard, for it frequently becomes the site of an anatomic variant in the terminal ileum, vermiform appendix, or cecum.

The aboral ileum is generally recognized as the relatively most important segment of the ileum. It is particularly rich in lymphatics. So large are the lymph nodes in the mesentery of the terminal small gut that in many mammals they serve as the first means of identifying the ileocolic junction during abdominal exploration. They are comparable with the glands of the neck and groin in size and in frequency of enlargement. The significance of these ileocolic lymphatics was recently brought out in the following case:

CASE I.—*Pneumococcus Peritonitis*.—T. G., 14 yrs. Male. Sudden attack of pain, vomiting, and right sided tenderness and rigidity. Laparotomy disclosed. "Terminal ileum contained lymph follicles which stood out visibly and lymph nodes in the mesentery of the terminal ileum enormously enlarged (from two to five centimeters in longest diameters). Appendectomy and drainage. Pure culture of pneumococci from exudate and from appendix. Rapid recovery.

Of no less interest if of less defensive value is the ileocolic sphincter. Like the ureterovesical and bilioduodenal sphincters it serves as a barrier against ascending infection. This function is happily shown in the above case. Of greater protective value than this "valve" is the neuromusculature of the terminal ileum. It has been said that the "valve" protects 10 per cent. and the neuromusculature 90 per cent., but it is obviously impossible to actually measure these two factors of safety. Comparative studies upon the ureter have shown that the neuromusculature safeguards the kidney above after the vesical sphincter has been destroyed but that the ureterovesical "valve" does not render the upper urinary tract secure after paralysis of the ureter.¹ The defensive interplay of the sphincter and small gut is no doubt made effective through the proximal colonic nodal center. Keith² has drawn attention to the great importance of this nervous tissue situated in the colonic collar about the end of the ileum in the coordination of gastric, enteric, and colonic motility. Our own studies have shown experimentally and clinically that dynamic changes in the duodenum follow obstruction of the end-ileum.³ The lymphatics, the "valve," the neuromusculature, and the proximal colonic nodal center unite to make the distal end of the small intestine one of the most important intestinal segments in the body.

Adhesions probably appendical in origin seldom get further than the appendix itself but the terminal ileum is occasionally caught in scar tissue. In some instances it is apparently the contracted mesentery of the appendix; in others it is an eschar in the mesentery of the terminal ileum, the remains of an old resolved lymph node.

CASE II.—*Terminal Ileal Obstruction*.—J. M., 40 yrs. Male. Paroxysmal sharp pain in right inguinal region with general nervousness and mental depression. Local tenderness. Laparotomy disclosed "Terminal ileum for

FIG. 1.—Case II, ileum constricted by inflammatory tissue.

8 cm. bound firmly to postcecal space by obstructing band. Portion of ileum immediately adjacent dilated. Appendix distended and congested at tip." Band divided and appendectomy. Discharged cured of symptoms on tenth day.

CASE III.—*Terminal Ileal Obstruction*.—A. H. 38 yrs. Male. Anorexia, vomiting, constipation, and pain in right lower quadrant. Diagnosed in one of large city hospitals as "gold-poisoning." Local tenderness. Laparotomy disclosed "Terminal ileum caught in dense

FIG. 2.—Case III, ileum constricted by scar tissue with enlarged gland, probably in mesentery of terminal ileum.

scar tissue at its antimesenteric border rotated caudad on long axis for 180 degrees, and fastened in postcecal region. This scar evidently arose from a broken-down and organized lymph node in the mesentery just under the terminal ileum. Appendix distended at tip." Band divided and appendectomy. Discharged entirely relieved on twelfth day.

The ileocolic sphincter has been routinely examined but in no instance to date has any indication arisen for valvular repair. An embryonal cord of tubal origin enters into abnormal relations with the end-ileum in the following:

CASE IV.—*Terminal Ileal Obstruction*.—H. H. 20 yrs. Female. Pain, tenderness, and rigidity in right lower quadrant. Laparotomy disclosed "... Right tube connected by a strong fibrous cord one inch from its fibrillated extremity to a cyst, 2 cm. in its long diameter, and by this cord and cyst to the right lateral border of the omentum. This adventitious cord was tautly drawn across the terminal ileum one inch from the 'valve.' The site of traction over the ileum was distinctly marked by a compression in the gut. The ileum met cecum at tip and fused with its mesial border before entering the colon." Cord with cyst divided at both ends and removed. Inflamed appendix removed. Recovery.

In many of the chronic gastrointestinal cases the appendix has outlived its functional usefulness and remains as an abnormal appendix. Under these

conditions it may be looked upon as a diverticulum or as a semiocluded and semiobstructed intestinal loop. Such a loop apparently becomes a source of irritating stimuli to the rest of the alimentary tube, particularly to the stomach. Impaction may con-

retention of bismuth in terminal twelve inches of ileum. Laparotomy disclosed a cecoappendix or infantile appendix well up and behind the ascending colon. This arrangement accounts for a more obliquely upward-directed ileum than usual and adhesions between the terminal ileum and under surface of the transverse colon.

FIG. 3.—Case IV, terminal ileum constricted by omental band firmly attached to a cyst of Morgagni; note the incomplete development of the ileocecum.

vert this semiocluded into a doubly occluded loop or acute suppurative appendicitis may supervene.⁷ Other appendices are faulty in passively serving as anchorage cords for the cecum in difficult positions. Appendicular gastralgia is relatively common; cecal obstruction in which the chronic appendix is an immediate causative factor is comparatively less common. (See Case VI.).

CASE V. Terminal Ileal Obstruction and Fused Ileocecum.—C. L. 24 yrs. Male. Constipation of 5-day type, pain in hypogastrium, and tenderness in right lower quadrant. Laparotomy disclosed "a parietocolic membrane firmly attached to ascending colon, thickened and peritoneal covered in the cecal portion, a chronically inflamed appendix retrocecal and retroperitoneal in its distal two thirds by passing through a rounded edged oval fenestra in parietocecal membrane, and a terminal ileum obstructed by scar tissue in its own and in the appendical mesenteries." Compare Cases III. and IV. Recovery.

The cecum normally measures $2\frac{1}{2}$ inches long by 3 inches wide. It usually rests upon the psoas muscle and is placed so that the apex projects beyond the inner border of that muscle in the male. In the female the apex lies internal to that muscle for the pelvis is broader, thus causing that muscle to deviate more to the right than in the male. The apex may be internal or external to Poupart's ligament, upon the pelvic brim, or within the pelvis and covered entirely by peritoneum.⁸ Variations in position are largely explainable on the basis of arrested descent. The cecum reaches the right iliac fossa in the eighth month of intrauterine life. A cessation of the rotation of the intestine on the axis of the superior mesenteric artery may occur at any stage and give rise to wide variations in the fixation of the organ. Such an arrest may leave the cecum on the left side of the abdomen, under the liver, above, or below the pelvic brim.⁹ Compare the following:

CASE VI. Arrested Descent of the Cecum.—M. S. 39 yrs. Male. Umbilical pain accentuated by straining at stool and seven-day constipation. Large cecocolon, tender ileocecum. No duodenal "cap" with a plus 24 hour

FIG. 4.—Case VI, arrested descent of cecoappendix.

Appendectomy was performed, the cecocolon freed, and raw surfaces over oral colon turned in by invaginating sutures taken along the longitudinal taeniae. Discharged on thirteenth day. Four months later reported daily bowel evacuations and no pain.

CASE VII. Excessive Rotation of the Cecum with the Ileum Entering from the Right.—K. J. 26 years. Female. Epigastric pain and two-day constipation. Local tenderness and slight rigidity in right lower quadrant. Laparotomy disclosed "The cecum and the ascending colon were firmly held in adhesive bands and in an inflammatory membrane arising from the right parietes.

FIG. 5.—Case VII, excessive rotation of the cecum with the ileum entering from the right.

The cecum was rotated upward and to the right so that the ileocolic sphincter was anterior and dextrad instead of mesiad while the appendix was behind both the lower end of the colon and the peritoneum. Furthermore, the distal end of the ileum was dilated, probably as the result of compression. Enterolysis. Appendectomy. Imbrication of the ascending colon for the oral twelve centimeters." Discharged on thirteenth day. Reported free from epigastric pain, and daily bowel evacuations four months later.

The cecum is so little developed in the new-born child that the size of the cecocolon approximately equals that of the small intestine. During middle life the cecum normally becomes extended.¹⁰ Variations in size, therefore, may be due to a faulty development which leaves the oral colon large or small or fixes the organ in such a difficult position that attempts to carry out its motor function are followed by dilatation. Similarly, too, congenital bands and membranes may continually hamper colonic emptying to such a degree that it eventually loses its normal contractility. It is furthermore conceivable that habitual constipation which in the

early stages involves distention of the proximal colon may so fatigue and wear out the normal colonic walls that eventually dilatation ensues. Dilatation of the cecum is probably essentially identical with dilatation of the stomach. In both conditions no microscopic changes have been discovered or evidence for believing the neuromuscular tissues diseased has been found. Experimentally in dogs and working from the standpoint of obstructive or dynamic dilatation it has been observed that:

"The semiocluded and excluded oral colon after ileosigmoidostomy may or may not enlarge; it more frequently does not—in 75 per cent. The microscopic appearance of the wall of the colon in two of the four animals was negative. Doubly occluded and excluded loops of colon may or may not enlarge. Of five animals two were dilated and three were contracted or of normal size—60 per cent. The contents of the dilated loops were faecal remains and large amounts of gas. One half of the bacterial contents of a three weeks' dog injected intravenously into a normal dog caused only a temporary partial paralysis of the hind legs. The microscopical findings as given by A. Fraser are as follows: '(1) Mucosa and submucosa normal. (2) Musculature, both layers from one half to one third thicker than those of the remaining colon; this "thickness" is due not to hypertrophy but to marked hydrops of the muscle fibres. There is no evidence of increase in muscle substance or in the number of the fibres. There is no evidence of inflammation. (3) Serosa shows a thick layer of granulation tissue especially at the line of suture.'"

From an examination with Fraser of material from twenty or more human colectomies obtained by others from individuals with marked cecal retention it must be admitted that none showed any recognizably gross pathology and that a few were apparently negative microscopically. The greater proportion revealed a mucosa that was normal or hypertrophied and a musculature that was pseudo hypertrophied due to hydrops of the muscle fibers. It has been pointed out that these changes in the dilated cecocolons observed above in many respects resemble the histology of early paralyzed voluntary muscle. Such are the laboratory data on clinically diagnosed colonic dilatation. After the normally distended or physiologically dilated cecocolons are eliminated from among the cases of cecal retention of undemonstrable mechanical origin it is possible that so few pathological ones will remain that they should be properly considered anomalous.

Other defects in growth at maturity are apparently due to faulty fusion or to imperfect cleavage. Note the common lateral wall of the terminal ileum and mesial wall of the cecum in the following:

CASE VIII. Common Ileal and Cecal Wall.—M. T. 36 years. Female. Paroxysmal right iliac pain, nervousness, and constipation. Tenderness in right lower quadrant. Other findings including the x-ray confirmatory of chronic appendicitis and obstructed terminal ileum. Laparotomy disclosed: "The ileum approached the tip of the cecum and, fusing with its mesial wall, ran upward for over one inch before entering the large gut. The appendix was long, distended, and chronically inflamed." Malformation so recorded, but not disturbed. Appendectomy. Reported greatly improved three months later.

Anomalous development of the ileum, appendix,

or cecum become of surgical interest when first recognized. These atypical structures are obviously operative when they definitely interfere with the comfort or welfare of the individual. When first seen anatomical variants should be described for future reference as potential sources of evil. Bands and membranes often in themselves innocent commonly give rise to seriously harmful adhesions when unwisely disturbed. Pathology at the site of the anomaly or removed from but none the less dependent upon it should determine an attempt at surgical correction. As a rule these right-lower-quadrant morphological variants are suspected but not discovered until the abdomen is opened for appendectomy or reopened for unfavorable after-results of an appendectomy.

The operative surgery varies with each respective case. The simplest mechanical means of relieving an obstructed ileum or cecum is enterolysis which consists in the freeing of the intestine from surgical adhesions. This should be accomplished with the greatest care and with the smallest amount of foreign substance for ties or for suture material. It is probable that the absorbable material attracts

FIG. 6.—Case VIII, common ileocecal wall.

the least reactionary adhesion-formation. When it is necessary to unravel a distorted cecocolon it is probably wise to turn in the resulting abraded serous surfaces. When there seems to be "stasis" of the cecum because of its size and length, Blake recommends imbrication or longitudinal tucking-in of the oral colon. In many instances appendectomy is sufficient. In those very few and isolated instances in which resection of a diseased cecum of cecocolon is called for the preservation of the terminal ileum, the ileocolic sphincter, and of a colonic ileal collar intact and terminal anastomosis between this collar and the cut edge of the remaining colon should be undertaken.⁸

616 MADISON AVENUE.

CONSERVATION OF BABY LIFE IN THE TENEMENT.*

By JACOB SOBEL, M.D.,

NEW YORK.

CHIEF, DIVISION OF BABY WELFARE, DEPARTMENT OF HEALTH,
NEW YORK CITY.

It has been well said, "Start the child on the right path and we need not worry about the man."

In these days, when destruction of human life is so commonplace, an invitation to discuss the conservation of baby life, as suggested by your Chairman in the title of my paper, is gratifying and stimulating. I was cautioned by your presiding officer that twenty minutes would be allowed me and, with characteristic executive ability, he advised me to dispense with all prelude and camouflage and to delve into the subject from the outset. Under the circumstances, a mere surface outline will be presented, in written form, and I will leave such amplification of the subject as is necessary to the lantern slide demonstration which will follow.

The warring countries have all learned as a result of this conflict that it pays to conserve the health and lives of their children. They know now as never before that the nation that has the best babies has the future. The saving of infant and child life has not only a commercial, industrial, social, and civil importance, but a military significance of no small magnitude. At no time in the world's history has the importance of saving children been more urgent or immediate. It has been estimated that if England had devoted the same attention to child welfare during the past forty years that she is giving the subject today, she would have had almost two million more men in the field. And what applies to England applies to all other countries.

We in this country have not suffered as yet from the reduction in birth rate and the increased infant mortality rate experienced by our Allies and enemies in the early years of the war, and because of this very fact it is wise and prudent that we prepare before similar conditions arise here. We should fortify ourselves against any such contingency by avoiding their pitfalls and mistakes and applying their constructive methods to our own child welfare work. This we are doing on a large scale and nowhere, perhaps, to a greater and higher degree than in New York City.

The control of infant and child morbidity and mortality in New York City, as it exists today, has been the result of progress along public health lines in two directions: (1) That prevention is superior to, and easier than correction; (2) That the saving of infant and child life is an all-year-round problem.

Not so many years ago the approach to the conservation of child life was through the channel of treating sick babies. Such a method was irrational and non-productive of results. "Keep the baby well" has taken the place of "Treat the sick baby" in our public health program—a method more rational, more constructive and more productive. Nor are we satisfied with limiting our activities to the summer months, as in former days. Babies require care and attention the year 'round, albeit the heated term is the most dangerous period for them.

*Read at a meeting of the Yorkville Medical Society, March 18, 1918.

With these basic facts before us, the tenement house was the most natural point of attack. It is here that the triad of baby-killers—poverty, ignorance and neglect—finds the largest number of victims. Ignorance, carelessness and neglect respond, after constant and repeated instruction and supervision, to education, although the difficulties surrounding the attack are great.

Poverty, while exceedingly difficult to meet, is not insurmountable. Poverty is always a serious problem in the life of the family unit; but in the life of the baby, it is doubly so. As Holt says, "It may not be true in adult life, but in infancy money may purchase not only health, it may purchase life, since it puts at the disposal of the infant the utmost resources of science—the best advice, the best food, and the best surroundings." Poverty must be approached from various angles, as due either to illness, alcoholism, non-employment, industrial limitations, irresponsibility, etc., and its control through social and industrial readjustment, would in itself make for a lowering of the morbidity and mortality of babies. Poverty, too, may be relative. We hear much today of the increased opportunities for employment and the better wage. With the purchasing power of the dollar reduced by more than half and the weekly wage of the worker advanced by from eighteen to twenty per cent., the workingman occupies, in effect, a less favorable position than in peace times.

The saving of baby life, therefore, becomes more of a socio-economic than a medical problem, more a question of education and prevention than of treatment, more a matter of housing, overcrowding, personal and home hygiene, family income, employment, alcoholism, gainful occupation of the mother, racial or religious prejudices, customs, and superstitions; in other words, more a question of environmental adjustment, industrial opportunities, living wage and civic pride than of caring for babies when they are sick.

It is from this standpoint that the conservation of baby life in the tenement is approached and for this purpose babyhood is divided arbitrarily into three periods: (1) the prenatal period; (2) infancy, under one year and (3) babyhood, from one to two years.

We have reached a point in the saving of baby life where, despite all our efforts, any further marked reduction will become increasingly difficult unless attention is directed to the baby before birth. For some reason or other—perhaps because of its greater tangibility—attention has been focused upon the baby after birth; and yet, when we consider that over forty per cent of all deaths under one year of age are due to congenital causes; that seventy-five per cent. of all deaths during the first month of life are due to these conditions; that more babies under one year of age die from congenital diseases than from respiratory and diarrheal diseases combined; that while the reduction in the death rate from diarrheal, respiratory, and contagious diseases during the past ten years has been marked, the death rate from congenital diseases has remained practically stationary, it will be readily appreciated how difficult the reduction of our infant death rate will be unless instruction and supervision of expectant mothers becomes more universal. Congenital deaths

admittedly bear little or no relation to hygienic or dietetic errors, but are rather due to causes operating before, during, or shortly after birth. Hence the need of guidance for the future mother.

For four years the Bureau of Child Hygiene of the Department of Health has designated a corps of eight special nurses for this work, performing the same in an intensive way. At the same time, all nurses of the bureau, especially those of the baby health stations, have advised expectant mothers whenever they met them officially. Registration as early in pregnancy as possible, periodic visits before birth, instruction and advice in diet, hygiene, clothing, bathing, fresh air, exercise, rest, care of the breasts, skin and teeth, importance of breast feeding, reference to private physicians whenever possible, urinary examination, visits to private physicians, hospitals, maternity institutions, examination for tuberculosis and the social diseases, social service assistance in the form of material relief, clothing, employment, etc., the maintenance of cooking classes and sewing classes for mothers, the preparation of the room and articles for confinement and for the baby, early admission to and examination at maternity centers and hospitals for cases presenting suspicious signs or symptoms, or histories of previous prolonged or complicated labor, home visits for one month post partum, supplemental literature—these are some of the ways and means whereby pregnancy is made safe and comforting for the future mothers.

The results of this work (*New York Medical Journal*, January 12 and 19, 1918) justify the conclusion that a more general application of this supervision throughout the city would result in a lower infant mortality rate, especially during the first month of life, fewer deaths from congenital diseases, fewer premature births, fewer accidents to mother and child, fewer cases of sore eyes, better home conditions and increased maternal nursing, fewer deliveries by midwives, increased birth registration, enhanced supervision of midwives and better care of babies that are, and that are to come. We do not maintain that prenatal instruction and supervision will avoid deaths from all conditions classified under the heading of congenital diseases and from all forces acting during intrauterine life. It is contended, however, that a very large number of deaths due to these causes are preventable.

With the birth of the baby, certain essentials—we may term them elementals—are necessary for safeguarding health and life, from the municipal standpoint, namely:

- (a) Reaching the baby as soon as possible after birth, before aggravated errors of hygiene and diet have handicapped him, reduced his resistance, and exposed him to disease.
- (b) Securing breast feeding, which is the remedy par excellence for the reduction of infant mortality.
- (c) Where artificial feeding is necessary, establishing centers whereat parents who are unable to pay may secure for their children a high-grade, safe, clean milk below the market price.
- (d) Affording individual care in the home by the mother, or, in cases of illegitimacy, or where the mothers must work, in the home of a

foster parent instead of in institutions or at the hands of irresponsible neighbors.

- (e) Giving opportunity for nursing mothers to secure an available supply of high-quality milk at a price commensurate with the family income.
- (f) Emphasizing the importance of prevention, of keeping the baby well rather than treating him after he has become ill.
- (g) Educating mothers by frequent and repeated advice, instruction and demonstration, on all matters relating to the proper care of the child: regularity of feeding, proper quantity of food, home and personal cleanliness, fresh air, proper clothing, bathing, care and preservation of food, avoidance of flies, importance of sleep, rest, and regular weighing, avoidance of pacifiers, demonstration of proper milk formulæ, icing of milk, prompt medical advice at the first signs of illness—in short, advice and practical demonstration of all the little details that make for strong, vigorous, and healthy babies.
- (h) Gaining the confidence and cooperation of the mothers by having municipal employees act as friendly visitors rather than inspectors. The public do not want to be inspected; they want to be helped and advised; they want nurses and doctors to take a personal interest in their welfare, and then they respond.
- (i) In cases of urgent need, where there is want, suffering and privation due to family illness, poverty, desertion, non-employment, etc., the granting of social-service assistance through the organized relief, charitable and philanthropic organizations and individuals in the form of temporary relief of milk, rent, fuel, food, clothing, shelter, medicine, medical and nursing service, employment, etc. Pauperization should always be avoided. Temporary assistance is given with a view to teaching them how to help themselves.
- (j) Coordinated and correlated cooperation of all child-caring agencies, in order to prevent duplication of effort and any needless waste of time and energy.
- (k) A realization that the saving of baby life is a community problem. It is everybody's business—the business of doctors, nurses, parents, teachers, social workers, citizens, as well as of the municipal health department.

All these, and more, are offered the baby of the tenement by the Department of Health of New York City through the Bureau of Child Hygiene, and the avenues through which we reach the babies and carry out the aforementioned program are, in the main, the baby health stations and the district or home visiting by nurses. It is no easy task to reach 141,000 babies born annually in New York City. Many of the babies who need care most never reach us because of the indifference or neglect of their parents. It is for that reason that our drive is in the two directions mentioned, the baby health stations and the district home visiting; the former for those mothers who come willingly and anxiously, the latter for those to whom we must go.

The baby health stations, of which there are fifty-nine in the Greater City, are preventive all-

year-round centers, dedicated to the policy of keeping babies well. Each station confines its activities to a given district, from which it draws its clientele, and within which it carries on its educational campaign. The stations are established after a critical and exhaustive analysis of locality needs as to infant mortality, birth rate, baby population, existence of other agencies performing similar work, congestion, economic status of the inhabitants, housing conditions, intelligence of mothers, and other social factors.

While milk is sold in large quantities—almost six million quarts annually—for babies who must be fed artificially for one reason or another, for nursing mothers, for expectant mothers, for anemic and poorly nourished older children, and for sick children and adults, the sale of milk is the least part of their usefulness.

We aim to emphasize the educational value of the stations and relegate the sale of milk to second place; not that pure milk is unimportant in the life of a baby artificially fed, but because we believe that the saving of infant and child life is due about 80 per cent. to education and 20 per cent. to pure milk. Milk, no matter how good the quality, if accompanied by improper hygiene, diet, and sanitary care, is a secondary factor as a life-saving measure.

Paradoxical as it may seem, the best baby health station, from a public-health viewpoint, is one that sells the least amount of milk for babies, because this shows either that the mothers are feeding the babies at the breast or that they are securing a high-grade milk in open market and using the baby health station for the educational opportunities afforded.

In point of fact, breast feeding is always advised, encouraged, and urged. No child is permitted to be fed artificially unless all efforts at breast feeding have failed and all necessary dietetic, hygienic, medical, and other measures have been tried. We agree entirely with Dr. MacMurchy that "a mother should not sublet her duty to a cow." Nor is weaning sanctioned unless the physician in charge is satisfied that there is no other recourse. Many mothers who, upon admission, have stated that they have ceased nursing, have been enabled to continue breast feeding in part or altogether by the perseverance of the doctor and nurse, for it must be remembered that many breasts apparently lost to babies can be made to functionate again after weeks of non-use and inactivity. The fact that 68 per cent. of the babies registered at the stations are breast fed exclusively, and 13 per cent. fed partially from the breast, bears testimony to our recognition of the importance in value of mother's milk.

At these stations, nurses and nurses' assistants are in attendance daily, physicians twice weekly. Every baby is thoroughly examined upon admission, weighed, advised, and full data recorded on a history form. Breast feeding is the first consideration. This being impossible, a formula is prescribed by the doctor, in writing, to fit the child in accordance with his age, weight, digestive capacity, and tolerance. The preparation of the formula is demonstrated by the nurse at the station and in the home until she is convinced that the mother understands. There is no fixed rule for

milk modification, and top milk, whole milk, percentage feeding, the caloric method, various diluents or supplemental foods as temporary expedients, are permitted the doctor in charge.

The responsibility for the proper growth, development and health of the child belongs to the doctor. Babies are weighed once a week, or more or less frequently, as indicated. Sick and delicate babies are urged to report at least once a week. Breast-fed and normal babies report weekly or twice a month.

Home visits by the nurses are made regularly—more frequently, of course, in the case of weak, ill, and delicate babies—and all necessary advice as to preparation and care of the food, bathing, clothing, ventilation, sleep, regularity of feeding, etc., is given at the station as well as in the home.

Mothers' classes are held by the nurses, at which the proper purchase, preparation, palatability, preservation and care of food are demonstrated with special reference to the family budget, the nutritional content, the needs of the children, and the racial psychology, for, after all, Owen Meredith was right when he said:

"We may live without poetry, music, and art;
We may live without conscience, and live without heart;
We may live without friends, we may live without books,
But civilized man cannot live without cooks."

In the fall and winter, mothers' classes on the prevention of respiratory diseases are held, at which the dangers of coughing, sneezing, and kissing, and the importance of cleanliness and fresh air, oral and nasal hygiene, and other measures, are discussed.

The weight of the baby is recorded in a special booklet given each mother, and a loss of weight, or stationary weight, is noted in red ink, a danger signal that added care and watchfulness are indicated. Literature on child care, in different languages, is also distributed.

The district is canvassed regularly by the nurses and nurses' assistants for new babies, and those of tender age, particularly under three months, are urged to attend. Almost 12 per cent. of the babies registered at the stations are under one month of age, while over 50 per cent. are under three months of age. The question of relief is kept in the background as much as possible, but when called for no effort is spared to secure it in full measure.

Cases of illness other than gastroenteritis and malnutrition are referred to private physicians, if able to pay; otherwise, they are referred to neighborhood hospitals and dispensaries. Even cases of gastroenteritis and malnutrition are referred to private physicians, if they are able to pay, and only if unable or unwilling to secure the services of a private physician are they treated at the station. Emergency treatment is given, however, to all children acutely ill, and provision is made for prompt admission to hospitals if they are unable to secure the services of a private physician.

The public have come to look upon these stations as preventoria, and not as dispensaries. During 1917 only 10 per cent. of the babies were ill with gastroenteritis upon admission, and 6 per cent.

were suffering from malnutrition. Approximately 48,000 babies under two years of age were registered at these stations in 1917, and over 85 per cent. were under one year of age. The registration has increased from year to year since the organization of this service in 1911, an expression of the confidence in which these stations are held by the public.

The fact that these educational stations or centers are open to the public the year round, that they provide for keeping babies well, that their basic policy is to encourage breast feeding, that they offer a high-grade milk for babies artificially fed, for nursing mothers and expectant mothers, at from 3½ to 4 cents below the prevailing market price, that they are community or neighborhood centers where information for the family as a unit can be readily secured, that they afford a social-service medium which brings comfort, cheer, and assistance in the needy homes, and that by systematic instruction and advice on child care and feeding they prevent diseases of the gastroenteric tract and nutrition and maintain a resistance which wards off general diseases, demonstrate what an important factor they are in the conservation of baby life.

It will be gathered from the foregoing remarks that the baby health station service combines an indoor and an outdoor or district service. As an additional safeguard surrounding the baby, the station service is supplemented by the home or district visiting of nurses during the summer months. Summertime has been termed the "baby's Waterloo," and while diarrheal diseases do not claim the large toll of infant deaths of years ago, and while we do not see so many of the severe or fulminating types of former days, the heated term calls for special precautions for the baby. Time there was when diarrheal diseases practically controlled or determined the infant-mortality curve, occupying first place in the list of baby-killing diseases. To-day we find it occupying third place, the non-enviable first position having been assumed by congenital diseases, with respiratory diseases second.

From the close until the opening of schools some of the nurses delegated to this service, one hundred and fifty in number, are assigned to special districts within or adjoining the baby health stations where the infant mortality is known to be high, and where there is a large infant population. Each nurse is held responsible for the supervision of one hundred and fifty infants throughout the summer. When, by reason of removal or death, or for other cause, a baby is no longer registered, another is taken up. Visits are made at least once every ten days in normal cases, and more frequently to those ill, puny, or delicate. Conferences are held daily with the physician in charge of the baby health station, and he visits all sick or delicate babies when needed. All necessary dietetic, hygienic, and other advice is given. Here, too, in this work, prevention is the keynote. "Keep the baby well" is the slogan.

At the end of the summer these babies are referred by special card to the nearest baby health station for a continuation course of instruction. Weak and delicate babies referred to in this way, who are not subsequently enrolled at the stations, are kept under constant supervision through home visits of the baby health station nurse, and thus

many who would be sacrificed through parental neglect are reclaimed to good health.

This service supervises, each summer, some fifteen to twenty thousand babies. Since 1911, when this work was started, 127,000 infants have been advised, of which 1,228 died, a death rate of less than 1 per cent. during the period of observation; a most encouraging showing, and an index of what could be accomplished if a sufficient nursing force were available to carry on this work the year round.

I have stated before that to reach by personal contact the 141,000 babies born annually in New York City is no easy task. We are, however, reaching in an educational way every newborn baby registered with the Department of Health by forwarding to the mother within ten days after receipt of the notification of birth an acknowledgment of such report, in the form of a letter signed by the Commissioner of Health, calling attention to the need and importance of infant care, together with a transcript of the birth record, signed by the Mayor and the Commissioner of Health, together with educational literature on preventive measures, in the form of a pamphlet entitled "Ten Commandments for Keeping the Baby Well," including a list of the baby health stations. This innovation was the result of an analysis made by the department, which showed that the mortality among children of native mothers was higher than among those of the so-called tenement population, which had been followed up by intensive work for many years.

While we are of the opinion that the best form of educational propaganda is through personal contact with the mother, in the absence of a sufficient force to reach every mother of the city we feel that this method will at least point the way to the facilities offered by the department, and awaken them to a realization of the importance of saving babies.

It would carry me too far afield of the limits of this paper to discuss at length the other measures adopted by the Bureau of Child Hygiene for the conservation of baby life in the tenements. A mere summary, therefore, will suffice:

1. A rigid supervision and control of 1,635 midwives, responsible for bringing into the world over 45,000 babies annually.
2. Licensing and supervision of some five thousand foster mothers, having under their immediate charge about eight thousand children, under permits issued by the Department of Health, which are revokable for cause.
3. Maintenance in public schools and baby health stations of Little Mothers' Leagues, organizations consisting of girls twelve years of age and over, upon whom the responsibility for the care of their little brothers and sisters frequently rests. These girls are given didactic and practical instruction in child diet and child care, and are made volunteer departmental allies in the saving of infant life. They take better care of their charges, they bring education into the home, and become better prepared for future motherhood.
4. Supervision of day nurseries—110 in number, with a registration of over 7,000 children—and temporary shelters where mothers who are forced to work or to enter hospitals for oper-

ations, illness, confinement, or other cause, may leave their babies during the day or night, thus securing that comfort and peace of mind which make for speedy convalescence.

5. Maintenance of an emergency corps of inspectors on duty day and night the year round, for first-aid treatment of sick babies, and for their prompt admission into hospitals and institutions.
6. Provision, through co-operation of philanthropic agencies, for the free distribution of ice, milk, and fuel, for boat excursions during the summer, for stay at summer convalescent homes or hospitals in case of need.
7. An organization known as the Babies' Welfare Association, a federation of over one hundred and thirty agencies interested in child welfare, with a central office in the Department of Health, which acts as a clearing house for all these agencies, unifying child-welfare activities without interfering with the individuality of any of them. Through this organization provision is made for the care of pregnant women prior to and after delivery, for prompt admission of sick babies into hospitals and institutions, for admission of babies into temporary shelters and nurseries, distribution of free ice, cooperation of relief agencies, a wet nurse registry, admission to baby health stations of babies discharged from maternity institutions or from outdoor maternity service or nurses' settlements. This type of organization should commend itself to all communities, and is applicable to cities of all sizes. This organization exemplifies the "one-for-all-and-all-for-one" principle, and has been a contributing factor of no small moment in the reduction of infant mortality in New York City in recent years.
8. Lectures, lantern-slide demonstrations, moving-picture exhibitions throughout the year by doctors and nurses at schools, settlements, churches, playgrounds, etc.

You will naturally ask, "What has all this accomplished?" Without desiring to burden you with statistics, permit me to say that the infant mortality rate in New York City was

In 1902.....	181
In 1907.....	144
In 1910.....	125
In 1917.....	88.8

In fifteen years the infant mortality rate in New York City has been more than cut in half. In terms of baby lives this means that if the rate of 1902 had prevailed in 1917, with its 141,000 births, over twelve thousand more babies would have died than was actually the case.

Perhaps it may not be amiss to state that in 1914 New York City had the lowest infant mortality rate of any of the ten largest cities of the United States, while in 1915, 1916, and 1917 St. Louis was the only one of the large cities that surpassed it. And even then, if we consider the Boroughs of Brooklyn and the Bronx, both of which have larger populations and higher birth rates than St. Louis, we find that both of them had lower infant mortality in 1916, and the Bronx a lower one in 1917, than

St. Louis. When it is remembered that New York is the most cosmopolitan city in the world, this record must be considered no small achievement.

But some will maintain that many of these babies may have died in the second, third, or later years, and that these results during the first year were transitory. It is conceded that the true index of efficient infant mortality control is the effect which such propaganda has upon the health and life of later childhood, and it is, therefore, all the more gratifying to be able to point to the fact that while the reduction of infant mortality from 1910 to 1917 was 29 per cent., the reduction between one and two years of age was 42 per cent., between two and five years of age 41 per cent., and under five years of age 36 per cent.

It is unfortunate that we have not at hand any available method for computing the reduction of infant and child morbidity brought about by this work, and that we must, of necessity, present mortality statistics. If, as has been estimated, there are at least ten cases of illness for every death—and there were 12,568 infant deaths during 1917—the economic gain or saving to the community, to say nothing of the prevention of family worry, anxiety, and unrest caused by illness, through the results of this work, is apparently enormous.

There is a natural order of things from which we cannot escape, and which follows in sequence as surely as does the night the day—better parents, better babies, better school children, better fathers and mothers, better citizens, better city, state, and nation. It is to this sequence that the saving of baby life is dedicated.

If the life of the baby in the tenement is to be safeguarded in war time, efforts at its conservation must be strengthened rather than relaxed, for when sacrifices come, as come they will, they must be made by the adult population in the interests of the baby.

The mortality rate of the community is usually considered a criterion for its municipal housekeeping. With one-sixth of all deaths at all ages occurring during the first year of life, and almost one-fourth at all ages occurring under five years of age, it can readily be understood what an important factor in the general mortality situation the conservation of baby life becomes.

Yes, the most dangerous occupation in the world is that of being a baby. Few hazards can compare with it. Less chance to live a week than a man of ninety; less likely to live a year than a man of eighty; less probability of surviving his first year than an aviator making ascensions daily for a year has of being alive at the end of that period, do you wonder how precarious an existence is that of a baby, and how necessary it is to forge about him every possible effort for the conservation of his health and life?

Family Grafts.—According to Perthes the supposed superiority of heterografts from near blood relatives over those from aliens does not work out always in practice. Upon a girl who had been scalped by a machinery accident transplants from her own skin and those from her sister were made side by side; but while the autotransplants healed in well the others were all absorbed. —*Correspondenz-Blatt für Schweizer Aerzte.*

AN EXPLANATION OF THE AUSTIN FLINT MURMUR; ALSO OF THE PRESYSTOLIC MURMUR OF MITRAL STENOSIS.

By OTTO V. HUFFMAN, M.D.,

BROOKLYN, NEW YORK.

LECTURER ON PHYSICAL DIAGNOSIS, LONG ISLAND COLLEGE HOSPITAL.

SINCE Austin Flint¹ described his observation of a presystolic apex murmur occurring in aortic regurgitation without associated disease of the mitral valve it has been confirmed repeatedly, especially by American clinicians; and from time to time there have been discussions as to how a presystolic thrill and murmur similar to those of mitral stenosis are produced in aortic regurgitation. The explanation of its occurrence, as given by Flint, is that in the extreme dilatation of the ventricle during diastole the mitral segments cannot be forced back against the wall, and, therefore, remaining in the blood current, that they produce a sort of relative narrowing and, in consequence, a vibratory murmur not unlike in quality the presystolic murmur of mitral stenosis. Broadbent, on the other hand, has suggested that the regurgitant current from the aorta impinging upon the anterior or aortic flap of the mitral valve may set it in vibration and thus produce the murmur. Gee² says that the explanation of this presystolic apex murmur first noted by Austin Flint is uncertain. Cabot³ writes: "How it is that a presystolic murmur can be produced at the apex in cases of aortic regurgitation has been much debated, but remains unknown." DaCosta⁴ offers the following explanation: "For its production dilatation of the left ventricle and incompetence of the aortic valve are regarded as the essential factors. Owing to the enlargement of the ventricular cavity, the anterior cusp of the mitral valve is displaced, during diastole, from its accustomed mural position, so that it projects into the rising tide of blood within the ventricle, and consequently becomes the target of two blood-streams coming from opposite directions—one regurgitating through a leaky aortic orifice and the other issuing (normally) from the mitral opening. By this mechanism vibrations of the cusp are set up toward the middle or end of the diastole, with the generation of a presystolic murmur and thrill appreciable at the apex." Futcher,⁵ in addition to mentioning the two possible causes cited above, states that the cause of the Flint murmur is given sometimes as the interference of two blood-streams. Elsner,⁶ after calling attention to the controversy over the true cause and significance of the Flint murmur, favors Flint's original contention, namely, that a functional narrowing of the mitral orifice during diastole (auricular systole) due to the pressure of the regurgitant stream on the underside of the mitral flap is the cause.

That the presystolic thrill and murmur of aortic insufficiency must more than likely be produced somewhat in the same manner as the presystolic thrill and murmur of mitral stenosis is true because it is generally agreed by careful observers that the Austin Flint murmur has the typical rumbling quality exactly like the murmur of mitral stenosis and that likewise it, too, is accompanied by a palpable thrill. It was quite natural that Flint

should have explained it by a so-called relative or functional stenosis of the mitral valve, that is, a stenosis due to one flap being partially closed by the force of the regurgitant stream from the aortic valve. (The term relative stenosis should be reserved to designate the case of an auriculo-ventricular ring being relatively smaller than it should be in proportion to the size of the auricle and the ventricle, although it is actually larger than a normal ring.) But there is another explanation which seems to me quite as plausible, viz.: The thrill and presystolic murmur at the mitral area are due to the vibrations set up by the churning of the blood in the ventricle by the small stream squirted into it from the small mitral orifice by the force of the hypertrophied and distended auricle in the case of mitral stenosis; or squirted back from the leaky aortic valve into the blood in the ventricle in the case of aortic regurgitation. In both cases the stream is squirted with considerable force, but it is only toward the end of diastole when the ventricle is practically full that the stream meets with considerable resistance. The stream shoots across the blood-filled ventricle in the direction of the apex, where it strikes the wall of the heart, causing the localized thrill and rumble.

The following rather crude experiment will serve to elucidate: Two rubber bulbs are connected by a nozzle; to begin with, one is squeezed empty and the other is filled with water, then the water in the latter is forced into the collapsed bulb. The natural aspirating effect of the latter facilitates the filling and there is little resistance to the inflowing stream until the bulb is almost full, when the churning caused by the stream in its transit through the water and its striking of and reflection from the wall give rise to the vibration which may be felt and heard at the site. The aspirating effect of the empty bulb is not unlike the aspirating effect of the ventricular walls as they relax. (Students should be cautioned against thinking of the blood as entering an empty space in the ventricle during diastole. It enters synchronously with the creation of the space, just as in the above experiment the water enters the collapsed bulb.)

In aortic incompetence the long diastolic blowing murmur is due to the vibration caused by the escape of the small stream, and this is not to be confounded with the *telediastolic*, i.e. presystolic thrill and rumble at the mitral area any more than if you will permit a crude comparison, the sizzle vibration of a garden hose nozzle is to be confounded with the rumble its stream causes when the nozzle is submerged in a bucket of water. If you were to apply your stethoscope at the nozzle you would hear the noise produced by the escape of the water under pressure; if you were to listen at the bottom of the bucket you would hear the loud rumble caused by the impact of the stream against the water in the bucket and also against the wall of the bucket.

In mitral stenosis we sometimes can distinguish the two different sounds produced by the stream: In early diastole we may hear at the mitral area the soft blowing murmur caused by the escape of the stream from the stenosed orifice; but in the later part of diastole this is masked by the rumble caused by the churning of the blood and the impact of this stream against the wall.

Medicolegal Notes.

"Practicing Medicine"—Removing Superfluous Hair.
—The New York Appellate Division holds, in an action to recover a balance alleged to be due on a contract for "professional services," that where the plaintiff stated to the defendant and her niece that she could remove superfluous hair from the niece's face, and undertook to treat and operate for such physical condition with the electric needle, she "practiced medicine" without being a licensed and registered physician, thus violating Public Health Law (Consol. Laws c. 45) art. 8, and could not recover. The practice of medicine is defined in the act as follows: "A person practises medicine within the meaning of this article, except as hereinafter stated, who holds himself out as being able to diagnose, treat, operate, or prescribe for any human disease, pain, injury, deformity, or physical condition, and who shall either offer or undertake, by any means or method, to diagnose, treat, operate, or prescribe for any human disease, pain, injury, deformity, or physical condition." §160, sub. 7. The court said: "The plaintiff urges that the treatment given by her does not come within the purview of the Public Health Law any more than would be the case if she employed what is known as massage; but it is obvious that the manipulation or rubbing or kneading of the surface of the body as used in massage is quite distinct from the treatment which the plaintiff gave. It is true that the General Term of the Supreme Court, in the case of *Smith v. Lane*, 24 Hun, 632, held that the practice of massage was not prohibited by the statute then in force regulating the practice of medicine, and that it was merely a species of nursing; but the rule laid down in that case was strongly criticised in the case of *People v. Allcutt*, 117 App. Div. 546, 102 N. Y. Supp. 678, where it was held that it was not necessary either to administer medicine or to use surgical instruments in order to come within the provisions of the Public Health Law. In the case of *Territory v. Newman*, 13 N. M. 98, 79 Pac. 706, 813, 68 L. R. A. 783, it was held by the Supreme Court of New Mexico, in a well-considered opinion, that even the method of treatment employed in that case, which was known as 'magnetic healing,' given by a man who advertised himself as a 'drugless doctor,' came within the prohibition of the statute of that state.

"In the case of *People v. John H. Woodbury Dermatological Institute* (N. Y. Law Journal, Jan. 15, 1908), where the Court of Special Sessions of the City of New York held the defendants, a corporation and its president, guilty of advertising to practice medicine within the meaning of Laws of 1907, c. 344, which contained in section 15 a definition of the practice of medicine similar to that in the present law, the record of the case on appeal shows that one of the deformities which the defendants advertised to cure was superfluous hair."

The court, after citing this and some other advertising matter, said:

"We do not need the statutory definition to determine that this is advertising 'to practice medicine' by a non-registered physician.

"The conviction was affirmed by the Appellate Division (*People v. John H. Woodbury Dermatological Institute*, 124 App. Div. 877, 109 N. Y. Supp. 578), and

by the Court of Appeals (*Id.*, 192 N. Y. 454, 85 N. E. 697)." The recent case of *People v. Cole*, 219 N. Y. 98, 113 N. E. 790, L. R. A. 1917, c. 816, is authority for the proposition that the statute applies to "every means and method that could * * * be used or claimed to be used to relieve or cure disease and infirmity," unless such means or method is within the exceptions contained in section 173 of the Public Health Law. It was not contended that the plaintiff in the present case was within any of these exceptions. The statute further provides that any person who shall practice medicine without license and registration or in violation of the provisions of the article shall be guilty of a misdemeanor, §174. "The definition of the term 'practice of medicine' contained in the statute and quoted above may be thought by some persons to be highly artificial. It includes, and was designed to include, many things not popularly considered as medical practice. But the wisdom of the law, if it be constitutional (and its constitutionality is not attacked in this case), is a matter for the consideration of the Legislature and not of the courts. Their duty is confined to the interpretation of the laws, or, in proper cases, to the determination of their constitutionality. It may well be argued that four years of medical study, including a thorough knowledge of anatomy, materia medica, hygiene, etc., in all their branches, are not requisite to equip a person properly to remove superfluous hair alone. Yet it can hardly be contended that persons engaging in that occupation should not be subject to some sort of regulation to insure proper skill and sanitation, such at least as the regulations affecting the practice of chiropody. Public Health Law, art. 13. The Legislature has seen fit to set a much higher standard, as I have attempted to show, and until the statute herein discussed is amended or abrogated the courts have no discretion but to enforce it."—*Engel v. Gerstenfeld*, 168 N. Y. Supp. 434.

Selling Instruments for Prevention of Conception.
Appeal was taken from a conviction for a violation of section 1142 of the New York Penal Law making it a misdemeanor for a person to sell or give away, or to advertise or offer for sale, any instrument or article, drug or medicine, for the prevention of conception, or to give information orally, stating when, where, or how such an instrument, article or medicine can be purchased or obtained. The appellant claimed that if this law is broad enough to prevent a physician from giving advice and help to his married patients in a proper case, it is an unreasonable police regulation, and therefore unconstitutional. It was held by the New York Court of Appeals, first, that as the defendant was not a physician, the rule applied that no one can plead the unconstitutionality of a law except the person affected thereby. Secondly, by section 1145 of the Penal Code, physicians are excepted from the provisions of this act under circumstances therein mentioned. This section reads: "An article or instrument used or applied by physicians lawfully practicing, or by their direction or prescription, for the cure or prevention of disease, is not an article of indecent or immoral nature or use, within this article. The supplying of such articles to such physicians or by their direction or prescription, is not an offense under this article." This exception in behalf of physicians does not permit advertisements regarding such matters, nor promiscuous advice to patients irrespective of their condition, but it is broad enough to protect the physician who in good faith gives such help or advice to a married person to cure or prevent disease. The protection thus afforded the physician would also extend to the druggist or vendor acting upon the physician's prescription or order. The judgment appealed from was affirmed.—*People vs. Sanger* (N. Y.) 118 N. E. 637.

Employment of Physician by Health Commission.
The Indiana Appellate Court holds that under the state statute of 1909, relating to county health commissioners, the act of a health commissioner in employing a physician to take care of and quarantine smallpox patients is binding on the county, in the absence of fraud, and the fact that the patients happen to be indigent, or that there is a township physician, is immaterial and not affected by the statute of 1914, providing that township trustees shall take care of the sick poor in a prompt, efficient manner.—*Board of Commissioners vs. Keine* (Ind.) 118 N. E. 595.

Military Medicine.

PATHOLOGY OF THE BLACK SOLDIER IN FRANCE.

IN *Le Caducée* for February 15 is a brief account of this subject, abstracted from the *Bulletin de la Société de Pathologie exotique* for November. The soldiers referred to are the Senegalese and others from French Africa, as studied in two camps, and the results may not hold good for all of these troops or for the American or British negro soldier. Pneumococcal disease in some form is extremely common, and gives rise to bronchopneumonias, meningitis, generalized sepsis, and another condition readily intelligible, but hitherto not known to exist, to wit: *pneumococcal erysipelas* (for want of a better name), as well as gangrenous lesions and acute pemphigus. It became evident also that men of the white race might develop some of these forms of cutaneous pneumococcal disease. The same germ is also capable of causing pneumococcal phlegmon or abscess and panophthalmitis.

Of a total of 52 cases of cerebrospinal meningitis in these blacks, 22 were examples of primary pneumococcus localization. These cases all ended fatally. There was never any cumulative incidence or suggestion of transmission. A frequent complication was nasal sinusitis, while general sepsis was at times present. The pneumonia cases were often septic, and the sepsis was sometimes primary. The Senegalese, in some cases, had the disease "standing," and these ambulatory cases were admitted only after the disease had fully developed so that its mode of evolution was unknown.

It was found that no less than 57 per cent. of the total morbidity of the blacks was due to the pneumococcus. This argues for the existence of a special sensitiveness to this germ due chiefly to change in climate and environment, but also very largely to defective hygiene—alcoholism, nicotinism, syphilis, and malaria being predisposing factors.

War Surgery in the Indian General Hospital in Mesopotamia.—Percival S. Connellan, I. M. S., writing in the *Bristol Medico-Chirurgical Journal* for December, 1917, says that during the advance to Bagdad it fell to his lot to treat a considerable number of wounded in the Indian General Hospital to which he was attached. They were situated about half way down the lines of communication and to a large extent their work was that of a clearing hospital combined with some of the advantages in equipment and staff of a general hospital. The difficulties of transport in this country are well known. So far as the sick and wounded were concerned it was done almost entirely by means of river steamers over a length of line of 300 miles, which suddenly became extended to over 500 miles in the short space of about two weeks. The conveyance of wounded was arranged by stages of one or two days, followed by a night's rest, until they reached Amarah, where for the first time they were able to get a bath and be put in some comfort into beds. Little can be done on a river transport ship beyond the feeding and changing of the dressings of the more serious cases. Much good

work was done in the field ambulances and clearing hospitals up the line, where every wound was dressed and urgent operations performed.

The equipment was that of a general hospital in tents, with an improvised operating theater in a hut containing good theater furniture, including two operating tables, and a high pressure sterilizer. A first class x-ray outfit was invaluable. The staff was small compared with that of a British hospital, Connellan's section of 200 beds having two medical officers, two subassistant surgeons—that valuable class of Indians trained in medicine and surgery, eight Sepoy ward orderlies, a couple of dressers, some servants, and finally one nursing sister, to whose care and devotion some of the patients owed their lives.

The character of the Indian Sepoy patient differs widely from that of the British "Tommy," though their anatomy and physiology are the same. One has to bear in mind that they are practically ignorant of the ways of western medicine, and broadly speaking, they have little faith in it, but they are capable of a great deal of faith in the individual who is administering that treatment, and the writer found well to do nothing to discourage that faith, which maxim might be said to hold good in one's attitude toward one's patient of whatever creed or nationality. Then, too, they are impatient to get home and have but one guide to progress, the presence or absence of pain, leaving their shattered limbs to the care of the doctor, so long as they remain painless, but often removing splints and dressings regardless of the consequences if uncomfortable, very much as a dumb animal would. Their physical power of endurance is great, but of mental resistance to disease there is very little.

The wounded arrived in batches, and as a general rule, they were found to be tired from the discomforts of their long journey and suffering from a condition of mental exhaustion that made them very irritable. They were at once put to bed with a complete change into hospital clothing.

The next essential was food, so each man was given a meal of whatever suited his condition best; for the more serious cases milk was the most asked for, as milk is to the Indian almost a stimulant and certainly a tonic. Hot soups or ordinary meals of meats, bread, and vegetables were provided for others. When the patients were comfortably fed and rested in their beds Connellan made it a practice to change every dressing; but he tried to do this with as little disturbance to the patient as possible, and only on rare occasions had he found it necessary or advisable to change the form of splinting or give the patient an anesthetic on the day of his arrival in hospital. His belief was that more harm than good is done by disturbing the man's first night's sleep in a comfortable bed by the nauseating taste of chloroform or the change in position of a somewhat stiffened or cramped limb. Morphine and soporifics were given unsparingly on the first night. By the next morning the patient's outlook on life is considerably improved, and he looks on his doctor with more confidence when he

finds that he does not think of his wound alone, and he is more ready to bear the pain involved in the more thorough cleaning of his wound or submit to being carried to the operating theater, which to the Sepoy on his first visit is more like a chamber of horrors than a place for a practice of the healing art.

In dealing with wounds Connellan's practice was to interfere with nature as little as is consistent with the ordinary laws of surgery and a due regard to the ultimate condition and usefulness of the wounded part. He regarded general resistance of the patient to sepsis as one of the most important factors in the healing of these wounds, and in this respect it has been observed that the Sepoy is more resistant to sepsis than the British soldier, perhaps, owing to years of untreated cuts and bruises in his work at home in the fields giving him a certain power of immunity in the same way as he undoubtedly has a higher immunity to water-borne and fly-carried disease.

Connellan looks to the mental condition as an important part of the general resistance to disease, and to this end he tried to keep the minds of his patients as healthily occupied and as free from worry as was possible in a country about which it has been said that "the devil owned Mesopotamia and hell, and he elected to live in hell and leave Mesopotamia to us."

Some Points in the Diagnosis of Amebic Dysentery.—Capt. John Spears, M.S., writing in the *Dublin Journal of Medical Sciences* for January, 1918, says that he heard a very distinguished protozoologist, Colonel Wenyon, state that in his opinion in the next great European war, if unfortunately such an event should come to pass, each soldier would be provided with an incinerator which would automatically destroy his feces. If one can picture to oneself a laboratory worker in the Mediterranean war zone, in the height of a dysenteric epidemic, with a daily dose of fifty to eighty stools to examine, and fully conscious that history will repeat itself on the following morning, one will gather that there is some basis for Wenyon's remarks. Referring to the laboratory examination of feces there are two essentials to success: (1) The stool must be fresh. (2) If possible, it should not be contaminated with urine, castor oil, lysol, etc. The full-grown *Entameba histolytica*, which alone appears in the stool during the acute attack is difficult to distinguish from *Entameba coli*. The points to watch are: (1) *Entameba histolytica* is more refractile and more greenish in appearance. (2) It is stated to be more active. This is a doubtful matter if the specimen is not fresh. (3) Its nucleus is harder to see, and its nuclear membrane has not as coarse granules as that of *Entameba coli*. (4) The contrast between ectoplasm and endoplasm is more marked in the *Entameba histolytica* type. (5) The most important and reliable point is that the *Entameba histolytica* ingests red blood cells, whereas the *Entameba coli* may ingest bacteria but not red blood cells. Spears states that this difference is the only one on which it is wise to base a diagnosis.

Infection is spread by the cysts alone; they are somewhat resistant, and can live outside the body

for quite a period of time, especially if kept damp. Flies are, in particular, conveyors of infection, as Wenyon's experiments in Alexandria proved. He fed flies on feces containing cysts and then gave the flies temporary diarrhea by means of a treacle mixture. On examining the flies' stools he found the cysts had been passed unchanged. Lastly, Spears mentions that in cases of those important complications of amebic dysentery, hepatitis and liver abscesses, the diagnosis should not depend on laboratory examination of stools. It is uncommon to find cysts in the stools when hepatitis has commenced, especially if only one smear of one stool is examined. In such cases the examination should be done in bulk, and a negative report should not have too much weight.

Rent for Cape May Hotel Too High.—The War Department finds that the rent for the Cape May, N. J., hotel is too high and has ordered the hotel returned to the owners at the expiration of the lease at the end of the fiscal year.

Army Medical Department Activities.—A review of the work done under Surgeon-General Gorgas during the first year of the war shows that the number of army hospitals in the United States has been increased from 7 to 63, and others are to be added. In the United States the bed capacity has been increased from 5,000 to 58,000, and is to be made 88,000 or 100,000. In France the bed capacity has been increased from nothing to 20 or 25 per cent. of the Expeditionary Forces. The total strength of the personnel of the Medical Department has been increased from 8,000 to 106,000. The officers have been increased from 900 to 18,000; the Army nurses from 375 to 7,000; the Ambulance Service from nothing to 6,000. The number of large Army laboratories has been increased from 12 to 150, and laboratories of all sizes from 100 to 500. The capacity of the Medical Training School has been increased from nothing to 21,000. During this time 150,000 psychological examinations have been made in addition to the ordinary physical examinations. The old idea of the Medical Department's work was to fix up sick and wounded men who could be returned to active service and to discharge the rest. Now the department must handle men chosen from civil life, under physical requirements far less rigidly than formerly, and work for the upbuilding of their fitness. Its work goes through all the stages of preparation for war and continues through until the war's sick and wounded are refitted for useful and remunerative places in civil life. The Medical Department plans all the hospitals and supplies all the personnel. It undertakes to raise the hygienic standards of the soldiers in camps, in transit, and in trench. Its recommendations largely determine matters of camp sanitation, including water supply, drainage, fly and mosquito menaces, and the disposal of waste. Since the declaration of war the Medical Department has developed a gas mask at least equivalent to that of any belligerent. These are now being manufactured by the Government. Gas defense schools have been established in every camp. Nutrition surveys have been made of all the larger

military camps, most of the aviation camps, and some posts and officers' training camps. Reconstruction hospitals are being provided on a more extensive scale than any other nation at war has attempted. The men taken from civil life into the army showed a death rate from disease of 6.6 per thousand for the week ending March 8, which is below that of men of military age in civil life, which the Census Bureau gives as 6.7. From September 1, through the winter the death rate varied from 2 to 15 per thousand per year, averaging just over 8 per thousand per year; the rate in civil life by months is not available. The prevalence of respiratory diseases has now reached so low a mark that they are no longer considered a problem. The general health of the troops is now excellent and the percentage of men out on sick report would be markedly low but for mumps, venereal disease, and some other ailments which have practically no death rate. This report describes among other things the work that is being done to furnish proper recreation and entertainment for the soldiers and states that mass athletics have been developed in the camps for their recreational value and their bearing on bettering the fighting efficiency of the men. Baseball, football, soccer, and boxing are the most popular camp pastimes. Athletic fields have been constructed in all the camps. There is not a red light district existing to-day within an effective radius of any war camp, according to Chairman Fosdick.

Work for Disabled Soldiers.—The National Association of Manufacturers is making a survey of the industrial field to determine in which branches of industry crippled and disabled soldiers will best fit. This organization has placed itself on record as opposed to having the problem of placing disabled soldiers handled by charitable organizations and believes that the industries should help these men to help themselves. Thus far the survey indicates that places may be found for these men in boiler making, machinery building, plate glass making, printing, watch making, coopering, cement manufacturing, band sawing, and clerical work.

Glass in Army Supplies.—Announcement is made from San Antonio, Texas, that the presence of ground glass in nine different articles of food shipped to the Ninetieth Division Commissary at Camp Travis has been definitely proven. Fifty members of officers' families and enlisted men have been made ill by eating of these articles of food. In the course of the investigation which has been in progress for several weeks it was found that one Austrian, two Germans, and a Turk were among the chemist's assistants who have been examining food samples until recently.

Campaign Against Coughing, Spitting, and Sneezing.—The Army Medical Corps, under the direction of Surgeon-General Gorgas, is undertaking an educational campaign against promiscuous coughing, sneezing, and spitting. Surgeon-General Gorgas emphasizes the fact that this campaign cannot be made a success without the fullest cooperation of the press and the public in keeping constantly before our soldiers and the public the menace which promiscuous coughing, sneezing, and spitting offer. He makes the formal state-

ment that "Respiratory diseases have caused practically all the sick and death rate in the Nation's new armies and this is the reason for a campaign which will be instrumental in diminishing the incidence of pneumonia, measles, diphtheria, mumps, meningitis, infantile paralysis, influenza, and tuberculosis."

Typhoid and Dysentery No Longer Menace Camps.—Figures given out from the office of the Surgeon-General of the Army show that there have been but eight deaths from typhoid fever in the army camps in the United States since September 17, 1917. There has not been a single death from dysentery and there are no cases under observation. The records show that but a single suspected case of typhoid fever is at present under observation. During the Spanish-American War the death rate from typhoid fever was 8.79 per thousand. If that rate were effective to-day the American armies, on the basis of 1,500,000 in the service, would have lost from 13,000 to 15,000 men from the ravages of these diseases alone.

Zionist Hospital Unit Ready.—The Zionist Hospital unit, equipped by the women's branch of the Zionist movement, at a cost of \$250,000, will sail for Palestine within a few days. The personnel of the unit consists of 41, of whom 15 are physicians. A hospital in Jerusalem has already been placed at the disposal of the unit, and a dispensary will be opened at once.

Women's Hospital Staff Ordered to Bordeaux.—Dr. Alice Gregory of the Women's Overseas Hospitals and a part of her staff, who have their headquarters at Paris, have been ordered to a station near Bordeaux, where they are to care for 3,000 refugees. The nurses remaining on this side have been called for and some of them have already sailed.

American Red Cross Work in France.—In connection with the announcement that the American Red Cross intends shortly to call for a further subscription of \$100,000,000 it presents a report from its Department for Military Affairs in France. The report notes a large development of canteen, rest stations, and other activities behind the American front line trenches. The recent German drive has created a new refugee problem for Paris, and the Department of Military Affairs has detailed a number of its workers to assist the civil authorities in caring for the refugees from the battle zone. The report gives in detail the large amount of food and clothing dispensed to the soldiers. A new hospital has been opened for American Army and Navy officers on the French coast and another hospital with 370 beds has been opened for enlisted men. The Bureau of Farms is now operating ten farms varying from three to one hundred acres in size, attached to different hospitals. The general hospital supplies service provides equipment for nearly 4,000 hospitals in France and recently has fitted a hospital train with the most modern apparatus for the French Army. In five villages back of the lines reconstruction work is well under way. At Marseilles the American Red Cross is establishing hospitals and nurseries in furtherance of its work for the welfare of French children.

New York, April 20, 1918.

MAYOR HYLAN'S ATTACK ON THE HEALTH DEPARTMENT.

THE time of the freebooter in political life has evidently not passed even yet. We must still be as watchful and wakeful and vigilant as we ever were lest he destroy the usefulness and efficacy of the institutions we have built up in all these years with anxious care and civic devotion. Just now there is a determined effort on the part of the present New York City administration to disrupt the Health Department. The bureaus of Laboratories, Public Health Education, Hospitals, Preventable Diseases, Foods and Drugs, Administration, and Child Hygiene have been declared to be under the ban of the law because they were created without an amendment of the City Charter. But twice, in 1911 and again in 1914, different Corporation Counsels of the city rendered opinions that the bureaus in question, created by the Board of Health and sanctioned by both the Board of Estimate and Apportionment and the Board of Aldermen, were instituted in conformity with the law. Section 1181 of the City Charter provides that: ". . . The board of health may likewise establish such other additional offices as it shall deem necessary for the proper discharge of the duties and powers of the health department in the several boroughs, with such force as may be essential thereto throughout the city as constituted by this act, but shall always maintain its chief office in the borough of Manhattan."

When the Charter was adopted our conception of public health work was not so broad as it is today, and only two bureaus in the Department of Health were specified, namely, the Bureau of the Registrar of Records and the Bureau of the Sanitary Superintendent. As the importance of certain activities became recognized, and the mechanism attendant upon geographical administration became more cumbersome and uneconomical, certain branches of the work were put on a functional basis. The contagious disease hospitals, the laboratories, the Municipal Sanatorium at Otisville, and later the bureau of child hygiene were gradually differentiated into separate divisions of the Department. In 1914, for purposes of proper coordination and securing greater efficiency of

service, all the activities of the Department of Health were subdivided into nine bureaus with clearly defined fields of work, duties, and responsibilities. It was a long step in the right direction and under it the Department of Health was able to render more effective service than ever before.

There is no perfect institution, and the organization of the Department of Health can undoubtedly be changed to make it still more effective. But this is evidently not the purpose of our worthy Mayor. His object in abolishing the bureaus is quite clearly to get rid of the directors, who, being civil service employees, cannot be discharged except for acts of incompetence or insubordination properly established; but if the bureaus are abolished, the directors will automatically cease to be.

The Mayor can then "reorganize" the Department and appoint "chiefs" to carry on its manifold duties. All of these chiefs will head new offices and can be appointed either without civil service examination, or if examinations should be required they can be conducted in a "proper" manner. This is what underlies the reorganization of the Health Department, ostensibly undertaken in the interests of "economy" and in strict compliance with the letter of the law. When the plan of the recent "investigation" of the Health Department became known, arousing intense popular indignation against its investigators, certain ingenious subordinates alleged "graft" in the Department as a basis for the contemplated sweeping reforms. This is an already somewhat overworked dodge, for it will be recalled that when Mayor Hylan planned to evade the law and appoint a coroner friend of his as Chief Medical Examiner of the City, criminal acts were imputed to the successful candidates on the certified Civil Service lists.

It is to the Public Health Committee of the New York Academy of Medicine that we owe the exposure of this attack on the Health Department, and it is in the publicity so brought about that the only hope of defeating the Mayor's attempt to deform this most important department of the city administration lies. The labor organizations have been quick to scent the danger to the lives of the children of the city that would follow the undoing of Dr. Josephine Baker's excellent work in the bureau of child hygiene (see, for example, the timely article by Dr. Sobel on p. 676), and the medical societies are equally prompt in insisting that the hand of the predatory politician be kept off. What has Commissioner Amster to say about this detestable work? Is he willing to forfeit by acquiescence in it, the good opinion of his colleagues and the reputation for honesty of endeavor which they have up to now accorded him?

THE DECLINING BIRTH RATE AND ITS SIGNIFICANCE.

THE declining birth rate for some long time has been a fruitful theme for discussion. The subject has been brought into greater prominence by the

war, which has greatly accentuated the value of child life; and at the same time, owing to the progressing scarcity of suitable food, has increased child mortality, and is having a serious effect on the physique and vitality of growing children. Before the war, in certain countries, the declining birth rate was a matter of great concern, and in Europe the subject of very careful investigation. In virtually every country of the civilized world the birth rate has declined during the past fifty years. France has exhibited the phenomenon in the most extreme degree.

An address of Louis L. Dublin, on the declining birth rate, given before the American Association for Advancement of Science, last December, is published in *Science*, March 1, 1918. He points out that in western Europe, at the beginning of the nineteenth century, France was the first of the three leading countries in population, the states now comprising the German Empire were second on the list, and the United Kingdom third. A century later the German Empire headed the list, and France was last. While the population of the German Empire had nearly trebled, and the United Kingdom had increased to two and one-half times its earlier numbers, the population of France had increased by less than one-half. This was due mainly to its declining birth rate. Great Britain had been affected in the same direction, but to a less extent, while the birth rate of the German Empire had declined the least of the three countries.

In America, the problem of the declining birth rate is somewhat ominous because of the decline among the native stock. True, the picture of the American population growth is favorable from a superficial standpoint, but this increase in our total population is chiefly owing to two factors: First, immigration; second, a high rate of increase in the foreign born. For example, in the New England States the proportion of the native white stock decreased from 52.3 per cent. of the total white population in 1890 to 40.3 per cent. in 1910. The decline in the birth rate in the United States has been selective. Dublin draws attention to the fact that in Massachusetts, where the most accurate statistics on birth rates can be found, there has been a continuous decrease in the birth rate during the past forty years, and moreover the decrease has been most marked in the native stock. The annual reports on births, marriages, and deaths of the Commonwealth of Massachusetts for 1914 show that in 1910 the native stock had a birth rate of 14.9 per thousand; the foreign-born birth rate was 49.1 per thousand. The selective nature of the declining birth rate is also demonstrated in special studies on the size of families of college graduates and of men of science. The graduates of colleges for women show the lowest birth-rate statistics.

In order that the stock may maintain itself without increase or decrease, according to Sprague ("Education and Race Suicide," *Journal of Hered-*

ity, April, 1915), the average number of children per family which must be born is increased to close on four. Dublin therefore asserts without hesitation that a large part of the native stock of this country is in this sense not maintaining itself. It is not producing the average number of children necessary to perpetuate the stock.

The writer is of the opinion that the State is largely responsible for this condition, because it has not provided for the youth of the country a system of education calculated to inculcate national ideals. Our young people have been taught to look out for the individual and not in terms of the common good. Dublin further thinks that the State should make provision to reward, either substantially or with esteem, the women who, realizing their obligation to the State, are willing to bring up families of normal size.

Materialism and selfishness are at the bottom the source of the evil. An increasingly large number of men and women will not marry, or, if they do marry, restrict the size of their family because they do not care to spend money on their education and bringing up. It is certain that unless the native-born Americans have more children than of late years the character of the population cannot but greatly alter. Quality may count more than quantity, but on the other hand quantity may swamp quality, and, after all, there would seem to be no valid reason why quality and quantity should not be combined.

GUNSHOT WOUNDS OF THE KNEE JOINT.

DURING the past year or so there have been many radical changes in the methods of treating certain varieties of gunshot wounds, and one of the most striking is the change which has taken place in the treatment of injuries of the knee-joint. About a year ago Sir Anthony Bowlby (*British Medical Journal*, June 2, 1917) called attention to the fact that a great change for the better had taken place in the results obtained in the treatment of wounded joints. He said that the first improvement was the abandonment of intraarticular drains. The next was the excision of the wound, the removal of any foreign body, the flushing of the joint, and in some cases the closure of the capsule and the insertion of a superficial drain. This finally led to the third step in advance, which he described as follows: "As soon as possible after the receipt of the injury—that is, in the casualty clearing station—the wound was excised, the joint opened, cleaned and irrigated, and then the whole wound in the synovial sac and superficial tissues was tightly closed." It was astonishing, he said, how seldom infection followed such treatment, even when fragments of shell or pieces of clothing had been removed from the joint; but for its success it was essential that the incisions around the wound edges should be carried clear of all infected tissues and that the strictest asepsis should be maintained.

A further important contribution to this subject by Capt. E. Tissington Tatlow, R.A.M.C.(T). appeared in the *British Journal of Surgery* for January, 1918. He reports in detail on 100 consecutive cases of gunshot wounds of the knee-joint which came under his care in one of the base hospitals in France. The following varieties of lesions were encountered in these 100 cases: Tear of the capsule only, 9 cases; through-and-through wound without bone injury, 13; through-and-through wound with bone injury, 25; retained foreign body in the joint without bone injury, 24; retained foreign body with bone injury 29 cases. The nature of the missile causing the injury was: Revolver bullet, 1; machine-gun bullets, 4; rifle bullets, 9; shrapnel balls, 9; and high-explosive fragments, 77. In this series 68 men had been operated upon at the casualty clearing station, and of these 14 required reoperation at the base hospital. The remaining 32 men had not been operated upon when they reached the base, and 20 of these were operated upon there. In his statistical summary Tatlow states that of the 100 cases 2 died, both after amputations; 4 were successfully amputated; 9 were successfully resected; and 12 were not operated upon. The remaining 73 cases were evacuated to England, after operation either at the base or at the clearing station, with a normal temperature and either healed or granulating wounds or, at most, a small discharging sinus.

Regarding the method of treatment at the base hospital Tatlow says that when there is a large foreign body free in the joint or protruding out of bone into the joint cavity it must be removed. He has made it a practice to remove any such foreign body of large size immediately, and states that the operative procedure has included excision of the tract, employment of a fresh set of instruments for the removal of the foreign body, a gentle mechanical flushing of the area in which it lay, the placing of about 15 grains of bismuth, iodoform, and paraffin paste into the joint, and, whenever possible, the suturing of the capsule and the complete closure of the wound. Special attention is paid to any bone injury and, after careful curettage, the paste above mentioned is placed in the resulting bone cavity. He believes that resection is the best treatment for streptococcal arthritis, but says that the ideal procedure would be so to treat every case at the casualty clearing station that secondary resection would be unnecessary. Acute arthritis due to the staphylococcus group, he states, can easily be treated by simple drainage methods; where there is no bone injury simple incision usually suffices, but if there is bone injury the Carrel-Dakin treatment gives the best results. He finds cases of pure *B. perfringens* infection of the joint very amenable to treatment; and usually after the removal of the foreign body and lavage these joints can be sutured; pyemic infection of the knee-joint by the streptococcus or other organism can be successfully treated by incision, mechanical lavage, the application of 15

grains of the bismuth-iodoform-paraffin paste, suture of the capsule, and skin closure. He also finds that in all these cases absolute immobilization of the joints is necessary.

If the above described methods are capable of giving such brilliant results under the conditions that obtain in the trenches and on the battlefield, it would certainly seem logical to adopt them in the treatment of joint injuries in civil practice. It will be interesting to note the attitude ultimately taken by American surgeons in France on this point; and if their experience coincides with that of the British and French surgeons, a great improvement in the results of treatment of joint injuries in civil practice after the war seems assured.

RAPID CURE OF SCARLET FEVER.

MARGOTTA writes on this subject in the *Giornale di Medicina Militare* for January 31. Professor Alecce has long experimented along lines suggested by the favorable results obtained years ago with phenol by Heubner and Eichhorst. The former injected the substance into the parenchyma of the tonsil at the outset of the disease, while the latter employed injections of 5 per cent. phenol. Alecce, having derived no marked benefit from serums, sought a sterilizing substance like salvarsan, and to a basis of chlorophenol he added quinine and camphor, the first named perhaps because of its supposed power over certain protozoa. These substances are so combined as to make a stable chemical substance, which is injected into the gluteal musculature. Many cases have now been treated, including the severe and severest. The effect was not a mere attenuation of symptoms, but a change in the clinical picture, which the author thinks confirms the belief that the active cause of the disease has been reached.

Margotta gives an outline of seven case histories. One youthful soldier was attacked May 7 with sore throat and fever, with pseudomembrane and exanthem. The first injection at once caused deferescence, but no change could be seen otherwise. In 24 hours a second injection was followed by paling of the rash and improvement in the throat. On the third day the improvement was held, and no further injections were given. The patient was pronounced cured on the eighth day. In a second case convalescence began on the sixth or seventh day. In most of the cases three injections were all that were needed. The patients were pronounced cured or convalescent in six to eight days; in one patient, who developed an otitis, the interval was ten days. The remedy appears in some way to antidote the circulating toxins, as shown by the sudden fall of temperature and improvement in the mental state. The positive result upon the exanthem, which pales out, appears to show a direct attack upon the principle which has caused the hyperemia. Naturally the injections should be begun at the onset of the disease.

OZONE IN THE PURIFICATION OF SWIMMING POOLS.

THE swimming pool and public bath must often be the means of spreading infection, and even were they not it would be desirable from the esthetic standpoint that the water in these public conveniences should be clean. Public Health Reports for March 1, 1918, contain a paper by Dr. Wallace A. Manheimer, in which is discussed the application of ozone to the purification of swimming pools. The conclusions are as follows: (1) Refiltration combined with disinfection of swimming-pool water is a standard procedure in the sanitary control of swimming pools. (2) The methods of disinfection hitherto employed are objectionable on one score or another. Ultraviolet light in actual practice has proved ineffective; copper sulphate in low dilutions is unreliable and in high concentration is not only costly, but produces a water disagreeable to swim in; chlorine compounds, while effective as disinfectants, require a technical control not available in swimming pools, and when used in excess produce objectionable taste and odor in the water. (3) Ozone when properly applied to the water of a swimming pool effectively purifies the water. When one part of ozone per million parts of water is used the result is sterile water. When half part ozone per million parts of water is used, a bacterial reduction of 99.8 per cent. results, except when too great an excess of air is introduced with the ozone. (4) A study of the cost of operation of the ozonator has shown that a current consumption of 2 kilowatts per day with alternating current and of 4 kilowatts per day with direct current, plus 1 cent calcium chloride represents the total operating cost for 60,000-gallon pool. This amounts to 11 to 15 cents per day with alternating current and to 21 to 29 cents a day with direct current. The cost of refilling the pool is at least \$30. The use of the ozonator decreases the number of times the pool must be emptied to such an extent that the cost of the installation is soon paid for. (5) The application of ozone to the purification of swimming pools is automatic in control, reliable in action, and inexpensive in application.

News of the Week.

A Protest Against Crippling the Health Department.—Dr. Walter B. James, president of the New York Academy of Medicine, Dr. Howard Canning Taylor, president of the Medical Society of the County of New York, Dr. Frederick C. Holden, president of the Medical Society of the County of Kings, and Dr. Abraham Jacobi joined in a public protest against Mayor Hylan's so-called investigation of the Health Department. This protest is in part as follows: "The proposal on the part of the city administration a few days ago to discharge the directors of seven of the nine bureaus of the Department of Health, first as a sweeping measure of economy and later, following an outburst of public indignation, on the ground that these bureaus are illegal, gives to the people of New York and especially to the poorer people, food for serious thought. . . . The Mayor's bitter aversion to all experts, testified to in numerous utterances both before and since the election, must

now cause a shudder of apprehension among all intelligent persons. . . . The New York City Health Department has always been the acknowledged leader among Health Departments of the country, and has been used as a model in the development of countless others. . . . It has never had to be ashamed of its achievements. Under its administration the death rate, especially the death rate of children, has steadily decreased until now New York has one of the lowest in the world. The sickness rate among the children of the poor has been enormously lowered. Typhoid fever, a disease of carelessness and filth, once a scourge here, has become an almost rare malady. Tuberculosis, cholera infantum, diphtheria, and other diseases all show a corresponding loss of numbers, and to-day one may give to the little children, with confidence, water from the tap and milk from the corner grocery, and it can no longer be said that in New York your babies are not safe unless you can buy bottled water for them or raise their milk on your own farm. This has not been brought about without the services of experts, and, like safety on the subways, it cannot be maintained except by experts. . . . The public is informed by the press that an investigation of the Department of Health is being carried on behind closed doors, and to this we object, for, as the department serves all the people and is paid for by the people, so the people have a right to know every move that is being made for it or against it. . . . We earnestly protest, in the name of the medical profession, against the discharge of the experienced and expert heads of divisions in the Department of Health unless after the most careful and unprejudiced consideration, and we assure the people of this city, first, that under the existing conditions competent substitutes for these skilled employees cannot be secured to-day at any price; and second, that any falling off in the quality of the work done by the Health Department will make this city again an intolerable place of abode except for the rich."

Bill Providing for Medical Inspection of Schools Withdrawn.—The Department of the Health of the State of Massachusetts has withdrawn from the Legislature its bill providing for extending medical inspection in the public and parochial schools of the State under the supervision of a state director. According to reports in the lay press no one appeared in behalf of the bill, while the medical profession recorded vigorous opposition to it. It was argued that the bill would be against the interests of the family physician and would impose a prohibitive cost on the cities and towns of the state.

Physicians Ask Hearing on Whitney Drug Bill.—The Medical Society of the State of New York, the Federation of Medical Economic Leagues, and the Association for Medical Defense of New York, through the acting president of the Society, Dr. Thomas H. Halsted of Syracuse, Dr. John A. Cutter, and Dr. John P. Davin of New York City have requested Governor Whitman to grant a hearing on the Whitney Drug bill before he takes action on the measure. It is claimed that among other objections the measure is revolutionary, unconstitutional, and dangerous to the welfare of the community and that

it will in effect bring about a lay and political control of purely medical duties at a time when medical men of military age are serving with the colors or else at home as volunteers for every kind of medical service required of them by the Government, and in consequence less able to act energetically in defense of their rights.

The Metropolitan Throat Hospital has just presented its annual report for last year which shows that it has given 5,851 treatments at the hospital during the year. In presenting the report announcement is made that the hospital is ready to contribute its resources to the Government for the treatment of soldiers and sailors and that the Government is considering the question of using the hospital.

Civil Service Examinations.—The Municipal Civil Service Commission of New York City announces three medical examinations for which application may be made at Room 1400, Municipal Building, Manhattan. Applicants must be citizens of the United States and residents of New York State. These examinations are as follows: 1. For *Assistant Medical Examiner*, at a salary of \$3,000 a year. Applications will be received until May 1, 1918, at 4 P. M. 2. For *Deputy Medical Superintendent, Grade 3 and 4*, at salaries varying from \$1,800 to \$2,400. There are at present two vacancies in the Department of Charities at \$2,520 per annum with maintenance. Applications will be received until April 29. 3. For *Pathologist* the duties of the position being to exercise independent judgment and to be responsible for pathological examinations and to perform research work under supervision. Applications will be received until April 30. For further particulars apply to the Municipal Civil Service Commission at the address given above.

The New London County Medical Association, at its annual meeting in New London Conn., on April 4, elected the following officers: *President*, Dr. L. F. LaPierre of Norwich; *Vice-President*, Dr. Daniel Sullivan of New London; *Secretary*, Dr. H. H. Heyer of New London; *Councilor*, Dr. C. C. Gildersleeve of Norwich.

New Maternity Center in New York.—As a part of the Baby Year work the Women's City Club is establishing a maternity center at 218 East Seventy-fourth Street. The work will include provision for securing expert treatment of symptoms indicating the development of abnormalities and special disease and aid for mothers and babies needing special care, special surgical supplies, etc. The committee is also working on a plan to provide food at a nominal cost for expectant mothers and to send working housekeepers to women with young babies, who otherwise would have to do the family work the second or third day after confinement.

Lepers Escape Guard.—A despatch from Bogota, Colombia, states that 300 lepers confined at the leper colony at Agua de Dios, near Bogota, have escaped their keepers and scattered through the surrounding district. The reason for their going is said to be dissatisfaction with the food furnished them.

Obituary Notes.—Dr. PERCIVAL LOUIS NAGIN, a graduate of the Long Island College Hospital, in 1914, died at his home in New York City, on April 5, aged 32 years.

Dr. ROBERT S. STEDMAN, a retired physician, living in Brooklyn, N. Y., died suddenly of heart disease on April 13. Dr. Stedman was born in Hartford in 1842 and was a graduate of the Medical Department of Columbia University (College of Physicians and Surgeons) in New York City.

Dr. SILVIO H. VON RUCK of Asheville, N. C., died of pneumonia in New York City on April 7, aged 42 years. He was a graduate of Bellevue Hospital Medical College, in 1899, and completed his studies in Europe. He was associated with his father, Dr. Karl Von Ruck, in the management of the Wingah Sanatorium and the Von Ruck Research Laboratory at Asheville, and the two had collaborated in several publications on tuberculosis.

Dr. CHARLES G. JOLLIFFE of Hasbrouck Heights, N. J., a graduate of the College of Physicians and Surgeons, Baltimore, in 1872 died in the Hackensack Hospital, on April 7, aged 69 years.

Dr. MAURICE J. SILVERMAN of New York City died suddenly of heart disease, while visiting a patient, on April 11, aged 53 years. He was a graduate of the New York University Medical School.

Dr. EDWARD MOTT MOORE, a graduate of the Buffalo Medical College, in 1874, a member of the American Surgical Association and the American Academy of Medicine, died at his home in Rochester, N. Y., on April 5, aged 68 years.

Dr. EDGAR P. LITTLE of Manor, Ga., died after a lingering illness in a local sanitarium, on March 14, aged 50 years. He was a graduate of the Atlanta Medical College in 1892.

Dr. B. F. JONES, a graduate of the Medical Department of Tulane University in 1878, died suddenly at his home in Goldfield, Colo., on March 18, aged 64 years.

Dr. JUSTUS R. CONKLING of Omaha, Neb., died of apoplexy at Dunedin, Fla., on March 20, aged 83 years. He was a graduate of Rush Medical College in 1859.

Dr. J. W. DUNCAN, one of the oldest physicians in Atlanta, Ga., a graduate of the Atlanta Medical College in 1868, died on March 11, aged 76 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE QUESTION OF VOLUNTARY HOSPITALS—CARE OF THE MOTHER AND INFANT BY THE STATE—THE INDIAN MEDICAL SERVICE—SIR JOHN PHILLIPS—DEATH OF DR. JAMES PEDDIE STEELE.

LONDON, March 28, 1918.

THE voluntary hospitals of London, forming a pattern for many institutions in other provincial capitals and large cities, have always been among the chief glories of the metropolis, and it is impossible to view their present financial condition without uneasiness, if only because that condition is in some cases so parlous that the very system under which they have hitherto thriven is threatened. In London this position, rendered obvious to every eye by the extra strain put upon the charities in so many directions by the war, has its particular difficulty because, despite the existence of many new and excellent provincial universities, London remains the center of the medical education of England and Wales, while largely ministering to the needs of

Scottish and Irish students; and the whole organization of the medical education of the kingdom is founded upon the voluntary hospital system. These are, briefly, the principles on which the association between the great voluntary hospitals and the great medical schools of London depends. The hospitals, relying upon voluntary subscriptions, donations, and legacies, owe no allegiance to local civic government. The money destined for them is administered by an unpaid committee of practical philanthropists, who recognize their responsibility toward the public by insuring that the funds are expended in carrying out the object of the donors, namely, in providing medical aid for the sick poor. The medical schools grew up around the hospitals because to the hospitals went the best exponents of medical art and science, and within their walls were to be found, and there only, multiple and ever-recurring examples of all the evils which the student, when duly qualified, would have to remedy among his patients. The staffs of the hospitals, being unpaid directly, have been and are paid indirectly by vending to that portion of the public who can afford to purchase, the experience gathered among their gratuitous charges; and the channel by which these distinguished doctors are placed in communication with the paying public is the students, who, having gone into medical practice, summon their old teachers to consultation, or recommend the public to apply to them when in trouble. The students, on their side, pay heavy fees for their medical education, concluded in the wards of a hospital, because in no other way can they be properly trained. School, student, staff, patient, and hospital under the voluntary system receive mutual benefits. The patient forms the material for the school, and is treated for nothing; the staff indirectly draw income through the students and give the treatment for nothing; the student pays a heavy fee for his education, but gets a very good one. The whole of this scheme is founded on the supposition, as far as the great London schools are concerned, that voluntary support will be forthcoming for the charities. Failing this, the state or the local taxes will have to finance the hospitals; the medical staffs will sooner or later be selected by laymen, for the staffs will have to be paid, and those who find the salaries will naturally want to find the men; the staffs will fall off in quality, and while the patients may be adequately treated, the standard of the teaching will inevitably decline. That is the outlook for the pessimist of the change in the management of the London hospitals, which poverty suggests may be near at hand; but a far wider outlook is permissible in view of the approaching Ministry of Health. Under a coordinating health authority any jurisdiction under which hospital management may come will receive the supervision of a powerful state department, and one of the first cares of this department will be to see that the facilities for medical education shall be as great as possible, and that the standards shall be high and easily maintained at a high level. There should, therefore, be no apprehension that owing to private interest or lack of the best attraction the important posts of the hospital staffs should fall into the wrong hands.

A bill, entitled the Maternity and Child Welfare

Bill, has been introduced in the House of Commons by Mr. Hayes Fisher, the president of the Local Government Board, and will come on for immediate debate, with a view to early legislation. It had been feared that for political convenience, or with the hope of saving time, the bill would be delayed until the promised bill proposing to enact the establishment of a Health Ministry was introduced, and it is a great relief to all who know the subject intimately to find that it is proposed at once to take steps to deal with the threat of increasing infant mortality. The bill applies, at any rate in its first stage, to any local authorities in England and Wales having the necessary powers, and these authorities are enjoined under it to immediately establish maternity and child-welfare centers. The expenses of the work will be defrayed by the provision of the existing act for the notification of births, and the results will be: first, the coordination in advanced localities of the many existing and differing charities and movements for the safeguarding of the lives of pregnant and parturient women and their offspring; and secondly, the initiation of such charities and movement in localities where hitherto they have not existed. The government will be congratulated by all medical men on having decided to tackle a task of supreme urgency.

The position of the Indian Medical Service has for some years now been a question of difficulty in many directions. The record of the service is a particularly fine one from the national point of view. Owing to the activity of the officers of the Service the amelioration of public health and climatic conditions in India has kept pace for over 100 years with the extension of the British rule, and where vast spreading diseases—an enormous epidemic of plague, for example—famines, or an outbreak of cholera have occurred, the officers of the Service have been resourceful and self-sacrificing beyond praise in their endeavors to stay the disasters and minimize their consequences. But the Service by its own activities, and by the scientific and administrative talent which it has been able to command, has created for itself in the most honorable way one enormous difficulty. Medical colleges have been founded in India, have been staffed by the officers of the Indian Medical Service, and as a result a large number of native students have been educated to a professional point at which they are perfectly able to discharge all ordinary medical and surgical functions in their native land, but to those native-educated men the Indian Medical Service itself is closed unless the entrance examination to it has been passed in the usual way, and *after* obtaining a position on the British Register by passing one of the statutory examinations for the purpose. The regulations, therefore, rule out almost all native talent from competition. Further, the officers of the Indian Medical Service are the only people with a statutory right to hold many of the medical appointments in India which carry the higher dignities and commensurate pay. The dilemma is obvious. On the one hand, for what purpose are the Indian students being educated to such a degree of proficiency if they are not allowed access to the prizes of the profession? On the other hand, what inducement is there for the young British doctor to expatriate himself, and to do very hard work in uncon-

genial circumstances for no great pay, if certain professional prizes are not thereby, and *thereby* only, placed within his reach. For a long time the Indian Medical Service was kept well manned, but it begins to look as though the position will not be maintained, the question of pay being the detrimental factor in the situation. The Indian Medical Service officer, comparing his position with members of the various branches of the Indian Civil Service, finds that he is underpaid and badly used in the matter of allowances, of holidays, and of promotion. He has not forgotten to make his side of the question well known, with the result that at the various British medical schools the Indian Medical Service is being no longer recommended by the teachers to their pupils, who are, on the contrary, advised that they can probably carry their talents to a better market. Therefore, the Service is not full; therefore, the chances of furlough and privilege for the existing members are slighter, and an added grievance results. If the personnel of the Indian Medical Service is to be kept full the Indian Government will have to make up its mind either to make concessions to native demand for greater scope or to grant higher pay to the European officers. Recent public pronouncements made by the Secretary of State for India say, in so many words, that Europeans are still required in the I. M. S., and that there is not an adequacy of trained Indians to hold all civil, military, and executive charges in India. The view appears to have been arrived at after quite fair consideration of the native claims, when it seems to follow as a matter of course that the pay and promotion of the I. M. S. will be improved. At the present moment the I. M. S. men do not share the benefits of other Indian services; their temporary allowances, specialists' pay, and so on, are calculated at a lower scale, and since the war broke out these inequalities have been aggravated. The Indian Government would be well advised to give the matter early consideration.

Sir John Phillips, one of the best-known gynecologists in London, and obstetric physician to Kings College Hospital, has been appointed physician to the Queen.

Dr. James Peddie Steele, for 40 years the correspondent in Italy of *The Lancet*, died suddenly some months ago. He was a famous Latin scholar and a poet, a collection of his elegant verses having just been published by Pillans and Wilson of Edinburgh.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

RECEPTION TO MAJOR MURPHY—RED CROSS RESCUES AVIATORS—HOSPITAL OF THE LAKESIDE UNIT—AMATEUR PLAYS—MORAL CONDITIONS EXCELLENT.

PARIS, March 4, 1918

MAJOR GRAYSON M. P. MURPHY, formerly American Red Cross Commissioner for Europe, who resigned several weeks ago in order to take an active commission in the army on General Pershing's staff, was given a reception at the American Red Cross headquarters, 4 Place de la Concorde, yesterday evening, and was presented with a token by his former associates. Major Murphy made a speech, in which he thanked them, and spoke of his very pleasant recollections of the work.

From a town in the Aisne comes news of a recent fire which destroyed the camp of a French aviation squadron. The fire occurred in the middle of the night, and members of the squadrilla lost all their effects. The resident delegate of the American Red Cross (Bureau of Reconstruction) was able to fit up the aviators with coats, trousers, mufflers, sweaters, socks, shoes, and even things like mattresses and cooking utensils. As the fliers had lost everything they had, this service of their American friends was keenly appreciated.

The American Red Cross reports that moving-picture machines and film service have been established in three more hospitals. The film service provides for the exhibition of three pictures each week. During the past month phonographs and records were sent to twenty new rest rooms at hospitals and camps in the American Army zone. Twenty-two additional hospitals also received a supply of games, such as checkers, chess, playing cards, puzzles, etc. About 2,000 novels were collected and sent to different hospitals. During January 700 magazines and 20,000 newspapers were distributed among the hospitals; in addition to these, several thousand old magazines and newspapers were sent out from headquarters.

The supply of tobacco at various hospitals was maintained. Each day many requests for recreational material of various kinds are being filed, including musical instruments, dictionaries, atlases, rubber stamps, stationery, sheet music, boxing gloves, wrestling mats, medicine balls, baseball outfit, etc. All members of the Red Cross organization are urged to contribute material to this department and inform their friends of the opportunity that is offered to make the hours of American soldiers in the hospitals more comfortable and enjoyable.

The administering of medicine and the dressing of wounds are the chief features of a base hospital. The Lakeside unit, in service in France since May, 1917, has found another side to base hospitaling. It has transformed one of its dining-rooms into a recreation room and theater. Now the wards are deserted during the day, save for the more seriously ill and wounded, and the barrack rooms are likewise empty, except at the check at night. The tables have been moved from the hall, a stage built at one end, the walls decorated, the floor oiled, curtains put up at the windows, and games and books installed. There are tables for the patients to write on, easy chairs to rest in and refight the battles in which they were wounded, magazines to read, games to play, etc. A billiard table has been placed in the hall.

A wounded sergeant has had charge of the redecorating of the hall and the construction of the stage. He has painted a complete set of scenery and a new curtain and has aided in the production of the plays. One of the features of the theatrical end of the new hall is that every member of the camp must take part. Sergeant Charles Couch is in charge of the production of the plays. So well received have been the first few sketches which the boys have put on that they are now working on a big minstrel show, real American style, which will make a tour of the camps and hospitals after it has been shown at their own hospital. On entertainment nights the officers and nurses are invited to

view the productions. Special matinees are held in the afternoon for the patients. Every man in the unit has done his share in making this new part of the hospital life a success, and every patient that goes away from the hospital is "strong" for the recreation hall and the theater. The nurses, too, have done their share. They have presented one sketch and have made silk amber shades and beads for the lamps in the room.

Much has been said and written about the moral conditions existing in France since the commencement of the war, and it is gratifying to have such a favorable report from one well qualified and who has made a special tour of our camps to study actual conditions. The Rev. W. M. Woodfin, Pittsburgh, Pa., associate secretary of the Presbyterian Board of Temperance, who came to France to study social conditions in relation to the United States Expeditionary Force, has completed his survey of the army. He says that he has found conditions very satisfactory, so far as morals are concerned. The facts, as he has gathered them, are even more gratifying than the official statements given out by the military authorities. He says that he has come into contact with thousands of soldiers and has found the moral conditions of the army very good.

Progress of Medical Science.

1. The Place of the Home, the Dispensary, the Sanatorium or Hospital in the Treatment of Tuberculosis (Value of Diet, Rest, Fresh Air, etc.).—Edward O. Otis points out that in clinical tuberculosis the basic principles of treatment are the same whether at home or in the sanatorium. The psychological element must be considered, however, and while one patient will do better in a sanatorium another will have a greater chance of recovery if treated at home. Rest, diet, fresh air, exercise, and the prompt correction of any complications comprise the treatment, but the painstaking and constant supervision of the physician is most essential wherever the treatment is given. The province of the dispensary is to make the diagnosis and to arrange for treatment, not to give treatment. When it is compelled to provide treatment, however, the dispensary must proceed on much the same plan as the "Class-Method" so successfully developed by Dr. Pratt. The Consumptive Hospital is intended primarily for advanced cases, and warm, well ventilated wards where the patients may be comfortable are the essential thing; open-air equipment is not necessary. The Sanatorium possesses certain advantages which do not exist in the home treatment, namely, favorable location, the presence of a skilled physician in case of emergency; the facts that the diet is arranged more scientifically in sanatoria where a dietitian is employed; that specific forms of treatment, such as the use of tuberculin or the employment of artificial pneumothorax, can best be carried out in an institution by experienced physicians, and that better discipline can be maintained in the case of patients with little self-control; and the force of example. On the other hand, where a large number of patients are treated *en masse* there must be a certain rigidity in the treatment and the patient may not be able to obtain the kind of food he has been accustomed to; moreover the monotony of diet tends to

loss of appetite, and there may be loneliness and homesickness. *Diet*: The average tuberculous patient requires from 500 to 700 calories of proteids, 1200 to 1500 calories of carbohydrates and 1300 to 1500 calories of fats. The physician should arrange the daily menu or at least give a list of nutritious and proper foods from which a selection may be made. It must be remembered that "a consumptive who does not eat is doomed." *Rest*: Absolute rest is indicated where there is an afternoon temperature above 99.5°. In any case patients should rest a considerable portion of the day, and at the commencement of the treatment it is wise to keep the patient at rest for two weeks. The disadvantage of complete rest throughout the course of treatment, although it may effect a cure, is that the morale of the patient is so enfeebled that his future usefulness is destroyed. It is of supreme importance, however, that absolute rest be enforced when there is fever. *Exercise*: This should be carefully prescribed, both as to kind and time, and constantly supervised; and should never be permitted while there is fever. Otis believes that gymnastic and breathing exercises are of no special value and may do harm. *Clothing*: The tuberculous subject usually requires more clothing than the normal person, but an excessive amount should not be worn. Finally, Otis points out that though the fundamental principles of treatment are few and simple, their successful application requires careful, painstaking and constant attention to the many details involved, and an individualization of each patient.

2. Health in War Industries.—Thomas F. Harrington points out the danger of overwork under the strain of the burden produced by the exigencies of the war, and shows that the great question of to-day is not whether the workers in war industries are standing, without evident injury, the strain of overtime, long shifts, Sunday and night work employment, but whether they can stand it for a long period; and, secondly, whether the toll to be collected later in the ill health, lack of efficiency, and in the development of organic disease can, in any measure, be compensated by the temporary increase in income and wages for any overtime employment. He also voices a warning as to the danger of nervous and physical shipwreck confronting leaders in public life, finance, and science, in this country, and states that a reorganization of the working program of these leaders is one of the most pressing problems of the day. Referring to the experience of European countries since the beginning of the war, Harrington speaks of the great danger from fatigue and the importance of so arranging periods of rest for industrial workers that the nervous system may have an opportunity of ridding itself of the accumulated poisons. The true signs of fatigue are diminished capacity; the output rapidly diminishes when the work period is carried beyond certain limits. In the case of women and young persons, particularly, long hours are both injurious and unprofitable; women cannot work continuously and profitably for more than five hours. Sunday work for both men and women has been proved to be neither profitable, healthful nor economical. The writer considers, however, that although night work has never been considered economical for men even, the time may come when women will have to undertake such work. Much could be done to conserve the health and efficiency of night workers by providing warm food for them during the night. Such workers require light, appetizing food that is easily digested.

2. **Earache and Its Management.**—Rufus B. Scarlett draws attention to the significance of earache, with its complications, and states that its seriousness is often not recognized. The character and location of the pain may be confusing in at least three conditions. (1) In furunculosis, it may be distinguished by the patient as anterior to the middle ear and as becoming more intense as the lobe of the ear is disturbed. (2) The distress in middle ear infection is usually centered in the ear, and not necessarily affected by motion of the lobe. (3) When the Eustachian tube is involved in an inflammatory process pain and tenderness usually extend down the neck along the course of the tube. Scarlett states that every physician should be able to detect the existence of any pathological condition of the drum or its neighboring structures and points out that sagging of the wall of the external canal is suggestive of involvement of the mastoid cells. For the relief of pain a saline cathartic should be given and dry heat applied; moist applications favor venous engorgement, soften the tissues, and hasten local necrosis. Rest in bed is essential. Attention to the nasopharynx and depletion of the tissues surrounding the orifice of the Eustachian tube is important in order to encourage drainage from the middle ear. The dropping of oily solutions into the external auditory canal is unwise. Should relief not be obtained within twelve hours an incision should be made in the tympanic membrane, especially if the presence of fluid in the middle ear is detected. In the majority of cases this can be done under local anesthesia, and to produce this various preparations have been suggested; the author has found a combination of the crystals of cocaine, carbolic acid, and menthol most satisfactory. Local applications of cocaine, eucaine, or alpin to an intact tympanic membrane produce little effect, as the external surface of the drum is covered by a dermal layer. Such solutions are effective if injected beneath the skin at or near the point of incision, but the injection is almost as painful as the incision would be without anesthesia. A preparation consisting of cocaine crystals, aniline oil, and absolute alcohol, and extensively advocated a few years ago, has been found to produce toxic symptoms. Should general anesthesia be deemed advisable, chloroform, ethyl chloride, or somnoform may be used; nitrous oxide is more troublesome. A free incision should be made by a *sharp-pointed* miniature bistoury at the point of greatest bulging. Care must be taken to avoid injury to the incus and stapes, and the point of the bistoury must not penetrate too deeply. After the incision has been made the canal should be mopped dry and a small wick of gauze loosely inserted to encourage drainage. The canal must subsequently be frequently cleansed with cotton, and as much moisture as possible eliminated. Should the discharge become copious a mild antiseptic is of value. Care of the nose and throat is essential, and as a certain relaxation of the drum membrane and intratympanic ligaments follows inflammation, precautions must be taken to guard against complications. The middle ear should be carefully inflated, at first daily, until all traces of congestion have disappeared, hearing has been restored, and the tympanic membrane retains its normal position.

1. **Angina Pectoris.**—E. Fletcher Ingals, with the collaboration of William R. Meeker, presents the results of his observations from a clinical standpoint on sixty cases of angina pectoris, of which thirty-two were true angina and twenty-eight pseudo angina. These cases were considered in conjunction with a careful study of Allbutt's work. The author points out that the pain in angina pectoris is not usually in the heart and the left arm, but rather along the course of the aorta and larger arteries and, in many cases, appears to have no relation to the condition of the myocardium or to the obstruction of the coronary arteries. He considers that the theory that the real seat of the disease is usually in the arterial walls and often in the external coat accounts for the incidence of the pain much better than the older view that the disease resulted from an affection of the coronary arteries with degeneration of the myocardium. The prognosis is more hopeful than is generally believed, under proper care and treatment, *a very important part of which is abundant rest with heart tonics as needed.* In the treatment, nitrates are among the most valuable remedies, but they are usually given in insufficient doses. The sublingual administration of fresh hypodermic tablets of nitroglycerine is of great value in relieving pain. It is of the utmost importance that these tablets should be fresh and that they should be given in sufficiently large doses. Given sublingually, the full effect of these tablets is experienced in from one to three minutes, whereas taken into the stomach the efficiency is reduced by half and the effect delayed for about ten minutes. When an attack comes on two or more tablets of 1/100 grain of nitroglycerine should be taken at once and repeated every few minutes until the desired effect is obtained. In one case, one hundred of these tablets were taken in one day in order to relieve a severe angina, and the pain did not return for three years. This remedy is of doubtful utility when given only three times a day in the conventional dose of 1/100 grain. The effect of amyl nitrite is not as certain as nitroglycerine. Sodium nitrite seems to possess some toxic property and is liable to disturb the stomach. Erythrol tetranitrate was found to cause more headache and did not relieve the pain as promptly as nitroglycerine, although its effects may be of longer duration. The heart may be protected against inhibition shock by the use of atropine in doses of 2 mg., or even 3/100 grain may be needed for some adults. Where there is a history of syphilis, potassium iodide or some arsenical preparation should be given. In a prolonged and severe attack, morphine or morphine and atropine may be given hypodermically, but they disturb the digestion, and it is better to rely on the nitrates if they will answer the purpose. Whiskey in quantities of about 3 ounces will also give relief. Hot applications over the sternum are helpful. The inhalation of chloroform has been recommended by Balfour, but is considered dangerous by Allbutt. In cases where the heart's action remains normal, the use of digitalis is contraindicated; it may be used with nux vomica if the action of the heart is feeble. The patient should lead a regular life, avoid overexertion, mental excitement, over-eating, and the use of tobacco, coffee, and sometimes tea and, what is of supreme importance, should rest, especially when the attacks are frequent. Essentially the same baths as those given at Nauheim may be taken at home, if nine pounds of sea salt and ten ounces of commercial calcium chloride are added to forty gallons of water, with or without carbonic acid gas.

I. An Address on the Selection of Candidates for the Air Service. Delivered Before the Medical Society of London on March 11, 1918.—H. Graeme Anderson pays a high tribute to the flying men. He says: "Nothing is too good for them, and it is up to us as a profession to strive in every way we can to save them from disaster, and should disaster overtake them to find the means to restore them to health again." He indicates the ways in which medical officers can help—by knowing the requirements of the aviator's life, by studying the psychology and physiology of flying, and by investigating the maladies commonly found among flying men. By such means standards of fitness could be drawn up, subject to modification from time to time, for the various flying duties. The aviator's duties subject him to the most intense strain to which the human nervous system can be subjected. As it has been aptly put, an aviator's life consists of "long spells of idleness punctuated by moments of intense fear." His physical requirements are a sound constitution, free from organic disease, and a fairly strong physique, in order to withstand altitude effects, such as cold, fatigue, and diminished oxygen. It is essential that there should be normal hearing and good muscle and equilibration sense. Good eyesight is of the utmost importance, and next to vision the most important question is that of temperament. The ideal aviator must have good judgment, be courageous, and not upset by fear, although conscious of the perils of his work. He must be cool in emergency, quick to decide and act, and alert; and a well-controlled imagination may be of advantage. Previous training in sports is usually found to be an advantage. An inquiry into the family history, as well as into the previous health of the candidate, will give an indication as to whether he will be able to stand the strain or not. Candidates for the Air Service should be made to undergo (1) a surgical examination, (2) a medical examination, (3) a special sense examination, preferably by experts in each line, and the final selection made on the total results by a medical selection committee. In the surgical examination the age, height, weight and general physique are considered. The age should be between 18 and 30 years; 24 is about the best age. As to height, if under 5 feet 2 inches the candidate would have difficulty in reaching the rudder bar or looking over the cockpit of the aeroplane. The weight does not count for so much as it formerly did, owing to the increased speed and climb of aeroplanes, but the lighter the candidate is the better. In considering the general physique particular attention should be paid to the abdominal muscles, where lack of tone would allow of splanchnic flooding and the possibility of fainting in the air. Any surgical defect, however slight, should be recorded. Any evidence of epilepsy, vertigo, migraine, persistent headaches, lack of concentration, or easily induced fatigue, whether the result of injury or not, should disqualify. Loss of cranial vault need not disqualify. Trunk injuries may disqualify, depending upon the amount of disablement and deformity. Cases of gunshot wounds of the thorax should not be rejected unless they fail to pass the altitude tests devised by Major M. Flack. Whether or not disabilities of the extremities should cause rejection depends upon the extent to which they interfere with the power to work the controls or use the machine gun. Old infantile paralysis cases should be rejected, and candidates suffering from venereal disease should be rejected temporarily. Before proceeding with the medical examination a careful record should be made of the candidate's previous occupation, habits, and mode of life; previous health, and family history. Anderson believes that excess in alcohol will ultimately beat the aviator and states that there seems little doubt that the action of alcohol is accentuated in the air. It is his experience that malarial cases rarely do well in aviation, and if they are allowed to fly at all he thinks they should do so in warm climates, as the cold precipitates malarial attacks. As is to be expected, candidates

with a history of neurasthenia, nervous breakdown, or shell shock do not do well. A history of recent tuberculosis of the lungs, asthma, chronic bronchitis, or pleurisy should cause rejection at once. The writer considers cases of real air-sickness to be rare and states that such are usually discovered while the candidate is still under dual control instruction; sea-sickness and train sickness are not grounds for rejection except for balloon work. In a consideration of the family history, the strain of war flying must be borne in mind. The renal, digestive, circulatory, respiratory and nervous systems must all be investigated and the presence of albumin and sugar in the urine, organic disease of the heart, or instability of the vasomotor system considered cause for rejection. Anderson refers to the valuable work done by Major Flack in working out tests of the candidate's respiratory capacity. The breath-holding test, in which the candidate is told to expire once as fully as possible, then to inspire fully and hold his breath, has proved of practical value. In this test a clip is placed on the nose and it has been found that a good pilot is able to hold his breath for from 45 to 60 seconds. The respiratory capacity should be 3000 c.c. or more. In the special sense examination vision is the first thing to be considered. There should be unaided normal vision in both eyes, and also normal color vision. Testing for night blindness is only of importance in grading pilots for night bombing. It is hardly necessary to test for stereoscopic vision. The condition of the teeth, throat, and nose is of importance, as most aviators fly with the mouth slightly open and a minor degree of oral sepsis is soon accentuated by the cold rush of air in flying. Septal deviation or enlarged turbinates will probably induce headache; and cases with adenoids, nasal polypi, or infective sinuses should be rejected until the necessary treatment has been carried out. It is important that hearing should be normal; each ear should be tested by forced whisper at a distance of 20 feet. Defective hearing in the pilot or air mechanic may lead to serious injury or even death, as should the aviator fail to catch the words "contact" or "switch off," in starting the engine preparatory to a flight the propeller may back fire and injure or kill the mechanic. Cases of chronic suppurative disease of the middle ear, or perforation of the tympanic membrane or cicatrices should be rejected. Anderson has found by experiment that the aviator is for the most part dependent on impressions conveyed through the eyes for his sense of balance during a flight; but he adds that further investigation is required in this direction. He gives the tests usually employed in considering the candidate's equilibration, muscle sense and vestibular reactions, and describes a test devised by himself which is similar to the D'Arsonval chronometer employed in France by Camus, Nepper, and Binet. Anderson suggests that a special flying school should be instituted where border-line pupils could be instructed in flying and that the results should be carefully recorded by a medical officer particularly interested in aviation.

3. The Prevention of the Spread of Epidemic Disease at Schools.—Major H. Morley Fletcher draws attention to the value of steam spraying, nasal douching and gargling in the prevention of epidemics. He suggests that a routine treatment of this nature would be of the utmost value in schools and institutions of all kinds, particularly in case of an outbreak of measles. A steam spraying apparatus was designed by Major Hine, the disinfecting agent used being chloramine-T. This agent, however, was later superseded by a zinc sulphate solution, as the latter was to be equally efficacious and better tolerated by most individuals. The method was introduced by Lieutenant-Colonel Gordon to disinfect carriers of cerebrospinal meningitis. Gordon also

introduced a system of nasal douching and gargling with potassium permanganate solution in normal saline, the solution being poured into the palm of the hand and snuffed up first one nostril and then the other. The fluid which passed down the naso-pharynx was spat out and the patient then gargled thoroughly with a fresh quantity of the fluid. This method was first used in the prevention of other infections in an outbreak of measles on a transport ship; the results were striking—no further cases occurred. Fletcher first tried the nasal douching in the First London General Hospital in December, 1917, when a soldier with fever and bronchitis was admitted to an overcrowded ward of forty-six beds. On the third day the soldier developed typical measles. No further cases of the infection occurred, with the exception of one, which developed in a V. A. D. nurse, who was the only person on the floor who had failed to carry out the measures ordered. Since then whenever a case of measles has occurred in the hospital the same precautions have been taken and have proved efficacious. No further contacts have developed. Apparatus for steam spraying is being installed at various naval and military centers and at Osborne and Dartmouth Naval Colleges. One has also been fitted up at St. Bartholomew's Hospital. With the approval of the Medical Research Committee and the assistance of Major Hine, Fletcher has fitted up an experimental boiler for steam spraying at one of the public schools in England, where 1 1/4 per cent. zinc sulphate is employed. At the same time a simple routine of nasal douching and gargling is carried out with 1 in 4000 potassium permanganate. A nasal glass tube or irrigator is used instead of the snuffing method. Cases of rubella, measles and chicken-pox have occurred without any secondary cases developing, but as yet it is too early to draw any definite conclusions. The results of the experiment will be published later. Fletcher, however, believes that frequent outbreaks of epidemic disease in schools, with the consequent loss of time and money, and even lives, could certainly be prevented by such measures as are indicated above.

Berliner klinische Wochenschrift.

January 21, 1918.

The Therapeutics of Strychnine.—E. Neisser remarks that use of strychnine has fallen into discredit among German physicians, while its use in other countries, particularly France, is becoming more and more general. Neisser does not hesitate to urge his confrères to employ this alkaloid more freely than in the past, its most frequent indications being: Traumatic shock, prolonged fevers, particularly typhoid; toxic coma from chloral, opium, or alcohol; neurasthenia and atonic cardiac states. (Neisser is evidently not in touch with George Crile's great work, for otherwise he could hardly advise strychnine in traumatic shock.) Intraspinal injections might be essayed in Neisser's opinion, for example, when spinal anesthesia assumes alarming conditions, the morbid process menacing the bulb. It may also be tried in infantile spinal paralysis. In this process Neisser injects strychnine in the spinal canal as soon as paralytic symptoms appear, even in very young infants.

Eosinophilia, Anaphylaxis, and the Nervous System.—D. Klinkert reviews the various conditions in which anaphylaxis, as well as eosinophilia, occur. The writer believes that clinically these conditions always become grafted on a weak point of the nervous system. Thus clinically one may unite the various forms of asthma, epilepsy, mucous colitides, angioneurotic edema, etc. Anaphylaxis in itself essentially consists in an "acquired idiosyncrasy." Klinkert next refers to analogous states which are realized in certain cumulative intoxications (quinine, salvarsan). Bringing together all these facts, the writer concludes that the idiosyncrasy is the result of a cumulative effect resulting from decreased or absent elimination. In the case of seric anaphylaxis the clinical phenomena measure the time taken by the organism to destroy the antigen until it can be eliminated by the urine. Klinkert endeavors to prove that the phenomena of passive anaphylaxis and antianaphylaxis bear out this view.

Münchener medizinische Wochenschrift.

January 22, 1918.

The Experimental Forcing Out of the Malarial Parasites into the Circulation.—S. Neuschlosz has been able to demonstrate that the exhibition of substances causing the spleen to contract (adrenalin, ergot, ext. of the hypophysis) can cause the malarial organisms contained in the splenic parenchyma to make their exit and enter the circulation. This blood infection, which allows one to detect latent malaria, is not accompanied by a typical thermic paroxysm. The organisms enter the blood from four to six hours after the injection, and this occurs more quickly when adrenalin has been used, but they remain longer in the blood after an injection of extract of hypophysis.

The Functional Exploration of the Renal Gland in Disease.—Schlayer and Beckmann esteem that the ordinary procedures for exploring the renal functions are greatly exaggerated and incapable of detecting the more minute changes. This reproach applies to qualitative methods which study the elimination of a given substance, as well as to quantitative methods which estimate the renal capacity to concentrate or dilute the urine. The writers resort to the study by employing the procedure of "the renal test meal" and from numerous researches partially reproduced in the form of diagrams they are led to the following conclusions: The normal kidney reacts to the test meal by great oscillations in hydric elimination and of concentration. On the other hand, the diseased kidney gives an elimination curve with less marked extremes and the tracings tend to approach a horizontal line. The test meals are thus distributed:

First breakfast: Coffee, 300 c.c.; 1 roll.

Second breakfast: Milk, 300 c.c.; 1 roll.

Noon lunch: Plate of broth, 150 c.c.; beefsteak, 150 gram.; potatoes.

Afternoon lunch: Coffee, 150 c.c.; 1 roll.

Supper: Mashed vegetables, 500 to 600 grams.

Total quantity of liquid = 1800 c.c.

Going still farther, the writers have studied the effect of another test meal diet containing the same total amount of liquid without any diuretic constituents. The comparative results of the two diets give data as to the degree of the pathological irritation undergone by the renal epithelium.

Deutsche medizinische Wochenschrift.

January 24, 1918.

The Diagnosis and Prognosis of Pulmonary Tuberculosis.—Goldscheider passes in review the various elements of diagnosis, as well as the estimate of the degrees of activity of tuberculous processes. He brings forward personal considerations only relating to the question of differential percussion of the apices, and states that the lesions are all the more extensive the greater their evidence obtained from a more energetic percussion of both apices. Exploration by lateral percussion of the apices during inspiratory ampliation of the lung may likewise detect very slight changes. Goldscheider also insists, among other things, on the little value of focus reaction produced by the injection of tuberculin, since this method relies too much on the subjective appreciation to be of any certain value. It is of great utility to determine the clinical type of the disease in each particular case.

The Prognosis of Pulmonary Tuberculosis.—F. Kraus believes that the prognosis can be established according to the clinical, pathological, or functional conditions offered, and it would appear that the latter are of more importance in this respect. Ranke has divided the evolution of tuberculosis into several phases, according to the bodily condition in various periods of infection. Lesions near the hilum due to the primary infection are quite possible to be seen by radiographs, and to distinguish them from latter outbreaks of the process. Such investigations will allow one to sort out those cases which will benefit by treatment in sanatoria. However, Kraus reproaches Ranke for not giving sufficient importance to the soil, and to the degree of predisposition offered by the patient. He likewise recalls that he has described a special form of tubercu-

losis undergoing evolution in "lymphatic" subjects (Kraus has evidently not read Trousseau's clinics, published over a half century ago, or he could not claim to have described a particular form of tuberculosis in "lymphatic" subjects, for the first time). For the practical application of his considerations Kraus refers the reader to De la Camp's work (Jena, 1917).

Experiences with Dysentery and Its Specific Serum.—J. Beyer believes that the useful effect of the serum has been proved, and is all the greater the sooner it is injected. He treats the more serious cases with bolus alba, or similar medication, combined with serotherapy.

Wiener medizinische Wochenschrift.

January 19, 1918.

Post-Operative Treatment.—H. S. Spitz in his article continued from the preceding issue, considers the question of the medico-mechanical procedures. More important than orthopedic apparatuses, which are becoming more and more complicated in construction, is a trained hospital personnel. By manual procedures, such a personnel can supplant almost any form of mechanical treatment. Finally, treatment by manual labor has the great advantage of giving the wounded man those movements which are the most essential, while its bad side is that the patient will often not use the injured limb, putting all the work on the uninjured ones. The corrective of this is to combine this treatment with mechanical measures. By these means it is possible to send back most cases of contractures to the service, likewise a number of paralytics. However, in the majority of the latter cases the results obtained by treatment only render the men fit for civil activities. Finally, a good stimulant for complete recovery is to give a leave of absence for one year after the patients leave the hospital.

The Treatment of Malignant Neoplasms of the Pharynx and Nasal Fossae with Radium.—L. Rethi relates the case of a man with a tumor of the palatine tonsil (lympho-sarcoma). An operation, combined with radium irradiations, completely cleaned up the pharyngeal cavity. The writer continued to treat the case by incising the enlarged lymph-nodes and then inserting radium tubes into them.

Two other cases were likewise satisfactorily treated by the same technique. Rethi lays down the general principles as follows: Cases which as still operable should be first treated surgically without any pre-operative treatment with radium, and only the inoperable cases are to be treated at once with radium. The writer questions whether or not certain operable cases are not improved by immediate radium treatment.

Wiener medizinische Wochenschrift.

February 2, 1918.

The Results of a New System of Infant Feeding.—C. von Pirquet, on account of the lack of foodstuffs due to war and the resulting difficulty for hospitals to nourish their patients, has been led to examine the question of infant feeding and has obtained good results from the viewpoint of development, as well as realizing a considerable saving by the application of the following general method: (1) The estimate, in nutritive unities, of foods, taking 1 gramme of milk as a standard; (2) the proportionality of the quantity of food estimated by the absorbing surface of the intestine. This is calculated after the square of the seated body (vertex-ischion distance). The tables made after the writer's calculations also allow one to estimate the best utilization of foods. Another advantage resides in the fact that the children, when they return to their homes, do not receive food of inferior quality to that given them at the hospital. The benefit acquired is not interfered with when the child returns to its familial feeding.

Fractures of the Upper Portion of the Femur from Rifle Bullets.—F. Kaspar has employed both Bardenheuer and Florschütz's methods of extension and suspension. He refers to the good results which are possible to attain without having to resort to other more complicated methods, such as those of Steinmann, Klapp, or Zuppinger, which are useful at base hospitals

at the rear. Fracture cases should be evacuated as soon as possible from the ambulances at the front to the rear. One should abstain from attempts at reduction in recently infected fractures, as permanent extension has a much more favorable effect.

Wiener medizinische Wochenschrift.

February 9, 1918.

Thalassotherapy in the Wounded.—J. Glaz states that a stay at the seaside is beneficial (1) for cases of pulmonary tuberculosis, on the condition that process of induration is at an end; catarrhal pneumonia, "humid" lesions at the apices and bronchial and tracheal catarrhal processes are to be excluded. (2) For cardiovascular affections, which abound among soldiers, partly due to moral shocks and still more to tobacco. (3) For the wounded, in cases of suppurating wounds, or ankyloses. (4) For neurasthenics and loss of general vitality. Rheumatic and malarial cases are not to be sent to the seaside.

Surgical Observations on the Oriental Front.—W. Koerting regards as principal factors in wound evolution: The first dressing and the kind of transportation offered. He insists upon the necessity of heat for shock cases or after hemorrhage. Heat may be supplied by hot drinks, bottles filled with hot water, heated bricks, etc. The writer describes an improvised water tank supplied with pedals. He is well pleased with the essays he has made in treating profusely secreting wounds with animal carbon, while the addition of iodoform still more favors the development of granulations. (Isotonic sea water has been employed in the French ambulances and base hospitals for the past three years with success in suppurating wounds. Sea water can be sterilized without in any way deteriorating its therapeutic effects. Maurice de Fleury has particularly studied the question in a paper published in 1915.)

9. Smallpox in Buenos Aires. Emilio R. Coni.
10. Medical Problems of the Great War. F. M. Fernandez.

5. On Congenital Syphilis.—Braulio Saenz, comparing the influence of the various generators of congenital syphilis, sums up his work by stating that after all the rôle played by the mother in the transmission of syphilis is very much more important than that of the father. In Saenz's opinion the mother is almost always responsible for the cases of congenital syphilis; although his opinion is not so radical as that of Matzenauer, who believes that paternal infection is impossible, yet he believes that the chances of infection through the father are really small.

Persistent Botal's Foramen in a Man Aged Fifty Years.—Menetrier and Wolff reported the case of a man admitted to the clinic with cyanosis, dyspnea and inability to speak. Despite cardiac stimulants he soon succumbed. Autopsy showed the presence of the above mentioned defect. The man had worked throughout at a laborious calling.—*La Presse Médicale*.

Kitt's Nephritis in Calves and Its Relationship to Human Nephritis.—Sakaguchi investigated the macular diffuse fibroplastic nephritis of the calf (Kitt) and pronounces it to be a true inflammatory process with lymphocytes, leucocytes and plasma cells. Confluence of the spots causes diffuse nephritis. But for the absence of vascular alterations this affection might end in the cirrhotic kidney. The affection can persist in the adult bovine, but as a rule involution occurs—a phenomenon which may also be possible in man.—*Frankfurter Zeitschrift f. Pathologie*.

Book Reviews.

MEDICAL WAR MANUAL NO. 3. MILITARY OPHTHALMIC SURGERY. By ALLEN GREENWOOD, M.D. Including a Chapter on Trachoma and Other Contagious Conjunctival Diseases by G. E. DE SCHWEINITZ, M.D., and a Chapter on Ocular Malingering by WALTER R. PARKER, M.D. Price, \$1.50. Philadelphia and London: Lea & Febiger, 1917.

THE joint authors of this volume are engaged in active military service and Dr. Greenwood has served at the fighting front in a British command. As a result the book gives the reader the entire benefit of the experience of British military oculists. The volume contains eight plates and sixteen text figures, most of the former illustrating trachoma. To the reviewer, who has had the opportunity of following up the literature of military ophthalmological surgery since the beginning of the war, the subject does not seem to be fully covered, to say nothing of exhausted. For example, there is no allusion to hemeralopia and other forms of trench blindness nor of syphilis as it affects the eye. We doubt the expediency of excluding medical affections in a work of this kind, for there is only one science of ophthalmology.

TECHNIC OF THE IRRIGATION TREATMENT OF WAR WOUNDS BY THE CARREL METHOD. By J. DUMAS and ANNE CARREL. Authorized translation by ADRIAN V. S. LAMBERT, M.D., Acting Professor of Surgery in the College of Physicians and Surgeons (Columbia University), New York. With an Introduction by W. W. KEEN, M.D., LL.D., F.R.C.S.(Hon.). Pages, 90, with 11 plates. Price, \$1.25. New York: Paul B. Hoeber, 1917.

THIS little book by Dumas and Dr. Alexis Carrel's wife was written primarily for the instruction of nurses and assistants, in order that they might have a clear and concise account of the various details of the technique and an accurate description of the apparatus used in carrying it out. The language is simple and direct and shorn of all theoretical considerations. There are six short sections, two appendices and a glossary of terms in French-English and English-French. A transcription of the section and appendix heading will sufficiently indicate the scope of the work. These are: "Materials used in the dressings; Preliminary remarks on the purpose of the microscopical examination of the wound secretions; The dressing; The irrigating apparatus; Setting up of the irrigating apparatus, and The technic of irrigation." The appendices cover the preparation of Dakin's solution (Daufresne's technique) and the microscopical examination of war wounds by the Carrel method (Dr. Vincent). The book gives a very clear idea of the Carrel method and the technique of its use.

A TEXT-BOOK ON GONORRHEA AND ITS COMPLICATIONS. By Dr. GEORGE LUYB. Late Assistant to the Urological Clinique, Hôpital Lariboisière, Paris; Prizeman of the Faculté de Médecine, Paris; Chief Medical Officer of the Urological Center at the Military Hospital, Versailles. Translated and Edited by ARTHUR FOERSTER, Captain R. A. M. C. (T. C.), M. R. C. S., L. R. C. P. (Lond); Late Resident Medical Officer, London Lock Hospital. Second Revised Edition, with 201 illustrations and three colored plates. Price, \$6.00. New York: William Wood and Co., 1917.

THE review of the original book, "Traité de la Blennorrhagie et de ses Complications," published in these columns, March 2, 1912, and the review of the first English Edition, published November 29, 1913, well apply to this second English edition. The translator confesses that he has "introduced but minor changes," which is due to the fact that "no radical advance in the knowledge and treatment of gonorrhea has been made during the last few years." These changes consist of an amplification of the sections on vaccine therapy, the use of colloidal silver preparations, and a short discussion of some procedures of questionable worth, such as galvanism, diathermy, and ionization. The arrangement of chapters has not been changed, neither is there extensive alteration in the text. The figures showing instruments of German manufacture have been omitted or replaced. The three colored plates, each containing

six figures, are very beautiful and true to nature. The first shows various parts of a normal urethra; the two others show pathological urethral lesions. The author must be congratulated on his continued optimism, for nowhere in the text or in the spirit of the book does one acquire a hint or a suspicion of the existence of an incurable urethral or prostatic gonorrhea. Because of its general excellence this edition will enjoy a continued popularity.

BALDNESS. Its Causes, Its Treatment and Its Prevention. By RICHARD W. MÜLLER, M.D. Price, \$2.00. New York: E. P. Dutton & Co., 1917.

THIS little work is written for the general practitioner and layman, and is therefore provided with a glossary of technical terms. It contains 121 illustrations in its 173 pages, and is based entirely upon the teachings of the leading authorities on alopecia, with several of whom the author has had personal correspondence. The list includes the names of Sabourand, Jackson (deceased), Joseph, and Darier. The quality of the book is therefore beyond criticism. The difficult subject of treatment is well handled and the author, from a large personal experience, commends the use of the Nagelschmidt lamp.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of Medicine, Medico-Chirurgical College Graduate School, University of Pennsylvania; Consulting Physician to the Jewish Hospital and to the Widener Home for Crippled Children; Officier de l'Instruction Publique, etc. Thirteenth Edition, with the Assistance of JOHN H. MUSSEN, Jr., B.S., M.D.; Associate in Medicine, University of Pennsylvania; Assistant Physician and Chief of Dispensary, Presbyterian Hospital. Price, \$7.50. Philadelphia and London: W. B. Saunders Company, 1917.

THERE is not much to be said of a thirteenth edition. When a work has gone through so many editions it may be taken for granted that it has filled a lack and that it has been kept up to date. However, the present edition has been thoroughly revised, some parts rewritten, and a considerable amount of new material added. The additions are treatment of tetanus, acidosis in dialyses chylothorax, etiology of aortic incompetency, treatment of asthma, diverticulitis, functional tests of hepatic insufficiency, Gaucher's disease, estimation of renal function, anaphylaxis of food intoxication, the pneumococci infections, focal sepsis, rat-bite fever, febris Wolhynica, and pyorrhea alveolaris. The section on diseases of the nervous system was practically rewritten by Dr. Charles S. Potts. Dr. John H. Mussen, Jr., had much to do with revising the various sections of the work.

The present edition of Dr. Anders' work well upholds the high reputation gained by former editions.

A COMPLETE SYSTEM OF NURSING. By A. MILLICENT ASHDOWN, Certificated King's College Hospital and Royal London Ophthalmic Hospital, Moorfields; Examiner in Nurses' Practical Work to Guy's Hospital, London, and the West London Hospital; Formerly Lecturer to the Nurses on Bandaging, etc., at King's College Hospital. With Numerous Illustrations and Diagrams. Price, \$5.00 net. London and Toronto: J. M. Dent and Sons, Ltd.; New York: E. P. Dutton and Co., 1917.

MISS HONNOR MORTEN some years ago wrote and published a very excellent work, entitled "A Complete System of Nursing." However, good as this book was, it became somewhat out of date, for nursing, like medicine and surgery, is ever progressing. Miss Ashdown, therefore, while preserving the title of Miss Morten's work, has rewritten it throughout. A large amount of useful information has been added and the value of the book has been enhanced by illustrations. In its present form "A Complete System of Nursing" fully lives up to its title, for it covers the whole range of nursing. The language employed is concise and to the point, all extraneous matter having been strictly excluded. The work can be strongly recommended to the notice of those desiring to learn all that comes within the province of the nurse. It is literally overflowing with valuable information compressed within a limited space.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held March 21, 1918.

THE SECOND VICE-PRESIDENT, DR. EDWIN B. CRAGIN,
IN THE CHAIR.

Physical Reconstruction.—Dr. PAUL BUDD MAGNUSON, Major, M.R.C.U.S.A., made this address, in which he stated that there was nothing particularly new in the reconstruction work as planned by the Surgeon General's Office; it was simply the co-ordination of a number of things that we had been doing over a considerable period of time. Many industries had been carrying on this work in a fashion for ten or fifteen years. In order to follow this reconstruction work from the beginning it might be well to follow the course of one of these men from the time he received his injury in the firing line. At the first dressing station a man was turned over to a group of specialists who were specially trained to care for the type of injury from which he was suffering. If, for instance, the man had an orthopedic injury he was cared for by a group of orthopedists. This was done because it was important that the man should be started right from the first. He should have the proper splints put on and have his injury properly immobilized at the first dressing station in order that he might be transported as comfortably as possible and that shock might be avoided as far as possible. In this way he would arrive at the evacuation hospital in better condition than if he had been subjected to much pain and discomfort during transportation. This was the first step in reconstruction. The evacuation hospital was equipped to do the surgery which the front line hospital could not do, and here more permanent dressings were applied. After twenty-four to forty-eight hours the man was taken back to the base hospital, and placed in charge of specialists in that class of injury to which he belonged. To ensure good care for the men very complete records were kept of every patient, and if a military surgeon had too many bad results he was removed from active duty. The men at the base hospitals who were permanently disabled were invalided home as soon as possible, because it was easier and cheaper to care for and feed them here than abroad. If a man was permanently unfitted for front line duty they contemplated putting him back to duty where he could be useful, as in clerical work, or in some special line of work as, for instance, stretching material on airplane wings. By following this procedure 100,000 now engaged in clerical work and in special work might be released for front line duty. Because a man was wounded was no reason to expect that he would immediately be discharged from the Army. For the reconstruction work the men would be sent to hospitals as near their former homes as possible, and it was planned to have these reconstruction hospitals so located that one could be reached from any part of the United States within twenty-four hours. The reconstruction of the disabled man at these hospitals did not mean only bone and joint work, but it meant making over every class of cripple, whether the disability required medical or surgical treatment. It meant fitting the man who had tuberculosis to make his living as well as the man who had had an amputation. These hospitals would be in charge of the best men who could be obtained, and as surgeons of this type were not very plentiful the hospitals would be large and there would be a number of assistant surgeons, and this would also leave more high-grade surgeons to care for the civil population. At these reconstruction hospitals a secondary amputation would often be found necessary, and in doing these the attempt would be made to obtain an end bearing stump. Then three or four weeks after the secondary amputation it was planned to fit the leg with a joint peg leg. Sixty to 70 per cent. of the leg amputations were above the knee. A peg leg suitable for this kind of an amputation had recently been invented by Major David M. Silver of Pittsburgh. It was a much better artificial leg than the Government had hitherto been able to get for \$100, and it cost but \$25. In this one thing alone Dr. Silver had earned his

salary as Major many times over. This joint peg leg was made of fiber and rubber. It was in three parts, a thigh, a lower leg, and a foot. Each part was so made that it could be cut off and shortened to the degree required by the individual case. There was no joint at the ankle, but a dowel on the ankle fitted into a socket in the lower leg. An instep hinge with a plug of rubber made a substitute for the ankle joint. With the leg clothed it would be very difficult for an observer to detect this peg leg on a practised user. Of the soldiers who returned to Canada 80 per cent. were capable of returning to their former occupation, and 20 per cent. required re-education. We had come to think of a hospital as a place where everyone was sick. These men in the reconstruction hospitals were not sick; aside from their crippling disability they were healthy, normal men. The only men who were really sick were the tuberculous, the shell shocked and the insane. Hence, the plan was to give these men work as soon as their disability permitted them to be about. It must be remembered that these soldiers had been looked upon as heroes, and a great deal made of them, and unless they were given something to do as soon as they were able to do it they were likely to become lazy and to wish to continue being simply heroes all the rest of their lives. Instruction could be begun in many instances along certain lines, while the men were still in bed. The patients were started on some form of re-education as soon as the surgeons decided that it was safe. This was directed from the surgical standpoint by the medical officer in consultation with the vocational officer and the disabled men themselves. Various factors must be taken into consideration in determining the disabled man's future occupation, such as the ability of the individual to perform certain kinds of labor from the physical standpoint as well as his mental equipment. In determining upon an occupation the local labor markets must be taken into consideration. The vocational officer must therefore be a diplomat in order to be able to direct the men wisely. Major Magnuson laid special emphasis on the fact that the men were turned out from the reconstruction schools 100 per cent. efficient in whatever line they took up, although they might be physically unfit for other lines. They would not turn out a man who could not compete successfully with other men in the same industry. For the purpose of making this known to manufacturers a campaign of education and publicity should be carried on. A fact worth bringing before the employer was that a man who was disabled was limited to one trade and he must needs stick to it, while the able-bodied man felt that he did not have to keep his job, as he could easily get another, for this reason the crippled man would often be found more efficient than a man not thus handicapped. In order to further a campaign of publicity they were now having moving pictures taken showing how the artificial appliances could be used and how cripples were enabled to do everything that a normal person could do. Instances were cited of what the crippled men who had posed for these pictures had accomplished. Much had been done in the way of reconstruction work abroad but there was no literature describing the details of the methods whereby an individual might become expert in using the various artificial appliances. They were now preparing a book giving pointers as to how to use artificial limbs. The reconstruction hospitals would be fully equipped to do high-class work in every department. They would be prepared to give hydro and electrotherapeutic treatment and massage, and there would be some little gymnasium apparatus, but not a great deal, as the plan was to use the curative workshop rather than the gymnasium in the therapeutic work. For instance, if a man had a stiff ankle, instead of being put on a Zander apparatus he was put to work on the lathe, or the gig saw, or any one of a hundred other things in which he might have an interest. He was then producing something concrete, and at the same time was deriving a therapeutic benefit from it. This was much better for the man mentally and also physically, for a massage treatment lasted but an hour, while with an employment he forgot any slight physical discomfort and did a great deal more than he would have done if he had been taking exercise simply as a therapeutic measure. As had been stated

above, only high-grade medical and surgical men would be put in charge of the reconstruction hospitals, for the country would not excuse any slipshod work. The medical profession would have the opportunity to make or break itself in this war. This reconstruction work that was to be done during the war brought up the question, "What is this going to do for industrial medicine and industrial surgery after the war?" Most of the work in industrial medicine and surgery had been done by young men who did it to get experience, and it had been more or less looked down upon by the profession. One reason for this was that the industries did not appreciate the value of this service, and did not pay enough to get high-class men. This was the time to prove to the industries that high-class medical and surgical care saved money and saved life, and if the medical profession grasped its opportunity the former condition of affairs would be changed after the war. The man engaged in industry was entitled to the best medical and surgical treatment obtainable. The man who was crippled in industry should be sent to an industrial school to be trained. The casualties in industries amounted to 17.2 per cent. of those engaged in industry, while in active warfare the casualties were only 25 per cent. Hence the problem of reconstruction for the cripples in industry was as great as that for the cripples caused by the war. There would be more men crippled in industry this year than the entire number of casualties in the American forces up to next January. We must not go back again to the slipshod and careless methods hitherto used with those injured in industry.

The Technical and Educational Side of Curative Work in Military Hospitals.—MAJOR MICHAEL W. MURRAY presented this paper in which he discussed the problem of re-establishing the soldier's morale and of returning him to civil life with such powers that he might again take his place as an independent wage earner. It was impossible to make a sharp distinction between the medical and the educational phases of the problem. At the beginning the work was wholly medical and surgical; at the end in most instances it had become entirely educational. The educator could perform a double service in the work of reconstruction by (1) assisting the medical officer in providing means of occupational therapy and (2) by readjusting the soldier or sailor to the requirements of civil life so that he might return to wage earning with the brightest possible future. Generally speaking the best therapeutic work would be that which aimed most directly and most visibly at increasing the man's wage-earning capacity, and at giving him a sense of increased power in his social and occupational relationships. While a man was lying in bed wondering what he would do in the future was the best time to make him resolve to do more than he had done in the past. Major Murray mentioned the various classes of men that would be met in the reconstruction hospitals, namely, machinists, carpenters, plumbers, automobile repairers, chauffeurs, metal workers, electricians, illiterate men, unskilled men, men with simply a common school education and no special training, men who had simply been doing odd jobs, etc., and showed what could be done with each class, either to improve the men technically for their own line of work, if they were physically capable of following it, or, if not able to follow their former occupations, to train them for a different line of work. The boy who left school at the age of fourteen, without completing his grammar school education and had worked at odd jobs, constituted a tremendously large class. These boys needed practical vocational guidance by men who knew what they could be taught and were acquainted with the industrial and commercial opportunities which existed, so that they might not be started in a line of work for which they were not fitted and in which there was little opportunity. The man with a common school education who had worked on a farm all his life and who was crippled with rheumatism for instance, so that he could do little actual work, and who wanted to follow no other occupation could be given special training on the scientific side of agriculture, simple practical farm accounts, and business management, and he would thus be fitted to manage a farm, working more with his head than with his hands. The educated man presented no difficult problem. He followed some line of commercial work,

such as accounting, salesmanship, teaching, and the other professions. The uneducated man, unable to use his hands in any skilled labor, presented a much more difficult problem. Major Murray related a number of instances in which men after the loss of one or more limbs had been able to earn more because of special training than they had earned before meeting with their accidents. He told of one man, a type of which we should probably have hundreds, who lost both legs. He had a splendid mind and had been half way through a chemistry course. While he was in the hospital it was suggested to him that he return to college and complete his course. He was delighted with the opportunity and took a new hold on life. There should be no break between the time these fellows were discharged from the hospital and the time they re-entered the schools or colleges which they left. It was to be hoped that such boys in addition to their compensation would be given an order which would amount to free tuition in some suitable school or college. The mental cases from all classes should be gotten out of doors for suitable agricultural and greenhouse work. A certain number of these men could undoubtedly do some of the occupational work such as basketry, willow work, rug braiding, knitting, etc. For this class of work special care should be taken in the selection of the occupation and the tools. For the educational work occupational therapists would be needed who had a wide knowledge of all phases of education, acquaintance with industrial demands and opportunities, familiarity with labor conditions, knowledge of educational means and possibilities, wide experience in educational administration, especially with the newer phases of education, as commercial, agricultural, vocational, and technical, knowledge of psychology, pedagogy and the realization that in a broader sense the work was all a part of the medical problem and that the man was not truly cured until he was back at work. The organization and equipment needed to maintain this problem consisted in personnel, buildings, equipment, including shops, drawing rooms, drafting, commercial facilities, and an equipment of the kind in all these lines that could be taken to the bedside. The speaker dwelt upon the advantages of interesting the men during convalescence in real work and on the necessity for the continuation of training after discharge under the advice of educators in industry or established schools. The reconstruction of the wounded soldier would undoubtedly demonstrate the value of this work in connection with army hospitals. It should show that if soldiers could be educated in hospitals, they could also be educated outside of the hospitals; and whether we had universal military training in the future or not, it should result in a strong educational division in the army.

Dr. W. GILL WYLIE expressed himself as much interested in the subjects presented, since they had a parallel in his experience. The Civil War demonstrated the value of the trained nurse in the Army and opened a field of usefulness for her in civil life. Dr. Wylie described conditions at Bellevue Hospital after the Civil War, related the circumstances under which the first training school for nurses in this country was established in connection with Bellevue Hospital, and told of his part in introducing the innovation. The introduction of the trained nurse into the hospital had improved the whole moral atmosphere, completely changing hospital life. He thought the reconstruction life as described, if carried into civil life, would work as great an improvement to society as the introduction of the trained nurse had done after the Civil War.

Dr. REGINALD H. SAYRE said that if the gentlemen had ever been in the lower part of the Grand Central Station they had seen a practical carrying out of a plan whereby men who had been damaged in railroad service were reinstated and were earning their own living. A large part of the work of the station was being carried on by men more or less damaged by railroad accidents. The corporation for many reasons kept these men out of sight, but they were doing the work of the station as well as anybody else could do it and in a way that was satisfactory to the corporation. The question of workmen's compensation had been touched upon. It was true that many corporations hesitated to give employment to anyone having a disability because they felt that if the employee had a disability at the start and then was in-

jured in their service the financial responsibility of the corporation would be augmented. Dr. Wiley had mentioned conditions after the Civil War, when at every street corner there was a man who had lost an arm or a leg grinding a hand organ. The establishment of the curative workshops would be an excellent thing to prevent the repetition of that tragedy, and of their therapeutic value there could be no doubt. In the treatment of infantile paralysis it had been repeatedly demonstrated that a child made much more progress if he could get the exercise he required by means of some toy or by riding a bicycle than merely by certain prescribed exercises and massage. The same principle was carried out in the treatment of spastic paraplegia, where they had the patient train his muscles by playing jack-straws. Working a lathe or jack plane was very much more interesting to a man than using a Zander apparatus.

Dr. S. ADOLPHUS KNOPF asked if he had understood Major Magnuson to say that they trained mechanics with tuberculosis to do clerical work. He thought that would be unwise, as a mechanic was accustomed to being out of doors and it would be a mistake to put him at an indoor occupation. Dr. Knopf asked what was being done for the tuberculosis patients employed in the workshops.

LIEUTENANT RUSSELL of Fort Jefferson thought that most of those who had joined the Army must have had before their minds a picture of the rank and file of the old soldiers of the Civil War. Those who had lost limbs had never been competent since the war and it was very discouraging to our young men to have the prospect of such helplessness before them. The plan that had been presented this evening should be published very widely so that young men thinking of entering the service might know what the Government was planning for them. Young men would be much more willing to join the Army if they knew that the Government would help them to make a livelihood if crippled after they quit the service.

MAJOR MAGNUSON, in reply to Captain Knopf's question, said that when he spoke of tuberculous men in the work shops, he had meant to convey the idea that the man suffering from tuberculosis was to receive the care and training he required to cure and reinstate him just as was the man who had had an amputation. The man suffering from tuberculosis would not be asked to do anything not conducive to his cure. He would not be given any work except under the guidance of the medical and vocational officers. There were certain kinds of outdoor work that would be very valuable to him. He would be treated along the lines now employed in the best tuberculosis sanatoria, and would be allowed to use up no energy until the tuberculous condition was quiescent. It was to be hoped that there would be two outcomes from the adoption of this plan. The one was that there would be no hand organs on the corners, that every cripple would be able to earn a livelihood, and the other was that in the future industrial cripples would have an equal opportunity with those crippled in the war. There was no reason why we should not take care of industrial cripples, for they were making just as much a sacrifice for their country as was the soldier, they were working in the service of humanity and of the Government, producing the things that were essential for the maintenance and comfort of their fellowmen. The slight extra cost of reconstruction for industrial cripples would amount to comparatively very little and when the schools previously described had once been established their operation would result in a very distinct saving, both to the State and to the individuals who would be trained there.

MAJOR MURRAY, in closing, emphasized the importance of having the educational work begin early during the convalescent period. He said he had been surprised at the amount that could be accomplished by a man who was able to sit up in bed. When a man was able to sit up in bed he could begin learning typewriting, drafting, and practically everything but shop work. Men had been able to learn a great deal about the mechanics of articles or apparatus that was not bulky while they were still in bed. By this plan of reconstruction there was no question that many men would be better off than though they had never had an accident that disabled them.

SECTION ON GYNECOLOGY AND OBSTETRICS.

Stated Meeting, Held February 26, 1918.

DR. WILBUR WARD IN THE CHAIR.

Hydatid Mole.—Dr. ALFRED M. HELLMAN reported this case, which occurred in a woman forty-four years of age, the mother of four children, the youngest being ten years of age. He said the history of this patient showed that four months ago menstruation was delayed a little. She then started spotting and thought she was pregnant. After examining the patient he, too, thought she was pregnant and that probably there was a fibroid back of the pregnancy. He advised that pregnancy be interrupted and this was decided upon. In removing the secundines a bunch of hydatids were caught in the forceps. On account of the patient's age and the possibility of the hydatid becoming malignant, a complete hysterectomy was performed. The uterus was found to be a little larger than it should have been.

Dr. M. A. SCHLENKER recalled three similar cases to the one just reported which occurred in the service of Dr. Knight. In the first of these the patient had just passed the menopause, and in this instance the cyst was discharged in its entirety. In the second case the woman went eight weeks past her menstrual period, then discharged part of her mole, and later another mass was discharged. The patient was then curetted, but there was very little mole remaining. The third patient was profoundly anemic and cachectic and, fearing malignancy, a hysterectomy was done. Hysterectomy was rather a radical procedure for this condition. If the uterus were emptied and the patient kept under observation the uterus might undergo involution and no further trouble follow; at the same time it was well known that some of these hydatids did undergo malignant degeneration.

Dr. ARNOLD STURMDORF asked Dr. Hellman whether he did a vaginal or abdominal hysterectomy and what condition of the ovaries was demonstrated. Clinically the cases of hydatid mole might be divided into two classes—namely, those in which the mole was spontaneously expelled *in toto* and those in which it was adherent from invasion of the uterine musculature. There was a certain established relationship between cystic ovaries, hydatid mole, and chorio-epithelioma. The exact nature of this relationship and its transitional stages were not clear, but it occurred with sufficient regularity to justify a hysterectomy in every case in which spontaneous expulsion of the mole had not occurred.

Dr. ARTHUR STEIN said that in a case of hydatid mole he did not think we should wait before resorting to a radical procedure. The right procedure in many cases was to do a total hysterectomy. Anyone who had watched this type of cases and had seen how rapidly they became malignant would agree that a total hysterectomy was a safe procedure. It was remarkable how a very little polyp of a hydatid mole left in the uterus would spread and degenerate into a chorio-epithelioma and reach a stage where it was inoperable; therefore, it was advisable to do a total hysterectomy in time.

Dr. S. WIENER said he wished to recall the other side of the picture. He had seen a large hydatid mole in a woman thirty-four years of age apparently firmly adherent, in which the uterus was thoroughly cleaned out and the woman had no further trouble. He did not think the teaching should be allowed to go out from this section that every case of hydatid mole should be subjected to hysterectomy. Dr. Wiener said he had personal knowledge of several cases in young women with hydatid moles in which the uterus was thoroughly cleaned out and the women had remained perfectly well and afterward had given birth to normal children. While he did not believe that we should perform a hysterectomy in every case of hydatid mole, he did believe that every such case should be kept under observation for months. With this precaution he believed that a fair proportion of hydatid moles could be treated by simple removal of the mole and, furthermore, as far as technic was concerned, one could perform a vaginal hysterectomy if it was advisable to investigate the entire endometrial surface to be sure

that the mole had been thoroughly removed, or that there was not a beginning chorio-epithelioma.

Dr. HELLMAN, in closing, replied that he did an abdominal hysterectomy. He sewed the cervix together and painted the entire vagina with iodine and then did the abdominal hysterectomy because he thought he could do a better and quicker operation in that way. In this case, taking into consideration the age of the patient and the fact that she had lost weight, a hysterectomy seemed the best thing to do. The specimen presented showed that there were a number of cysts on both the ovaries and the tubes.

Hydrosalpinx with Twisted Pedicle Simulating Ectopic Pregnancy.—Dr. ARTHUR STEIN reported this case. He stated that the woman was thirty-nine years of age, had one child and had never been pregnant since that time. The woman gave a history of having had a period September 12, then the middle of October, and again the beginning of November. He saw her for the first time on November 23, after she had been seized with excruciating pain in the lower abdomen and hemorrhage from the vagina. She was at that time in a state of collapse. Her temperature was normal, pulse 84. Examination showed that she had a retroflexed uterus and to the left, occupying the site of the adnexa, was an indefinite mass, about the size of a small cucumber. The diagnosis of ectopic pregnancy was made and the patient transferred to the hospital. Upon opening the abdomen the mass was found which was shown in the specimen. The mass was dark red in color and twisted around the pedicle four times. The right tube was also diseased, being transformed into a hydrosalpinx. A double salpingectomy was done. Examination of the specimen showed it to be a hydrosalpinx which had become twisted and hemorrhagic.

Dr. STEIN exhibited a second specimen, which he said fitted in very well with this one. The patient from whom the specimen was removed was a woman, thirty-three years of age, who was never pregnant. She was seized with acute pain in the lower left abdomen. On examination a large mass was found and a diagnosis was made of tumor on the left side. It was thought to be an ectopic pregnancy. On opening the abdomen a tumor with a twisted pedicle was found and on opening this it was found to be an old pyosalpinx which produced symptoms simulating an ectopic pregnancy. These specimens were presented because they were interesting and not very common. A fact that was also of interest was that nowhere were there any adhesions whatsoever.

Gangrene of the Uterus Due to Twisted Pedicle of Small Submucous Myoma.—Dr. ARTHUR STEIN presented this specimen, which he said was taken from a woman sixty-one years of age. She was examined by the speaker three years ago and was perfectly well. When she was again seen she gave a history of having had a foul pussy discharge for five weeks. On examination the uterus was found to be enlarged to about twice the size of the specimen. A curettage was done. Examination of the scrapings showed deep-seated multiple abscesses in the uterine wall. At the time of the curettage very foul pus was evacuated. After the curettage there was a rise in temperature to 103, 104 and 105 F., and there was a great increase in the amount of the discharge, as one would have expected, the amount being tremendous and the odor intolerable. A total extirpation of the uterus was then done. The uterus was dark, deep black, and soft. The entire uterine wall up to the peritoneum was absolutely black. The diagnosis was clearly gangrene of the entire uterus. It had started from a little myoma and the entire uterus had become infected. The pelvic veins were free. The patient made an absolutely smooth recovery.

Dr. THOMPSON T. SWEENEY said that Dr. Stein in his first case mentioned that there were rather marked pus tubes and no adhesions. This was interesting, as it showed that the infection was being overcome and that there was no exudate. He mentioned this because it was an example of the way in which nature would absorb an exudate and to call attention to the fact that in mild forms of gonorrheal salpingitis it was always wise to give the tubes a chance to recover through natural processes. There were many women who had

had a gonorrheal salpingitis who had overcome the infection and had borne children afterward. It was interesting to see how in these cases nature would absorb the exudate and protect the ovaries and tubes from permanent damage.

Dr. GRAN mentioned that cases of infected tubes were of two distinct classes; in one class adhesions formed and in the other they did not. It was in the cases in which adhesions did not form that the twist occurred. The type of case that Dr. Stein presented was that in which the pus tubes did not cause an exudate and no adhesions formed.

Dr. STEIN, in closing, said he also thought there never were any adhesions. The appearance of the specimen would lead one to believe that there had been no adhesions. The most interesting feature of the case was that, while there was a pus tube on one side, the tube on the opposite side was so hard that it gave one the impression that he was dealing with a myoma. The specimens were shown to demonstrate that it was not always easy even with the specimen before one's eyes to say whether he had hemato-hydrosalpinx or an ectopic pregnancy. In both of these cases they thought they were dealing with an ectopic and found later that they were mistaken.

A Case of Cesarean Section in Twin Pregnancy with Unusual Complications.—Dr. WALT P. CONWAY of Atlantic City presented this communication. He said the patient was forty-one and a half years of age. Her earlier history had no bearing on the case. She was married at the age of forty years and had had no miscarriages or abortions. During the last two months of pregnancy she suffered from considerable pain over the abdomen, constipation, and loss of appetite. For a week prior to her admission to the hospital she was ill with peritonitis. She was admitted to the Atlantic City Hospital on May 30, 1917, with a diagnosis of twin pregnancy at term and peritonitis. She had a slight albuminuria and a two plus Wassermann. After she had had pains for forty-eight hours and was almost exhausted an attempt was made to dilate and deliver with forceps under general anesthesia. The os was so rigid that delivery at this time was abandoned. Though the condition of the patient was not satisfactory, cesarean section was decided upon in the interest of the child, although a dead fetus was expected. On opening the abdomen an enormous uterus was found, very adherent to the parietal peritoneum and with the mesentery adherent to the fundus. After freeing the uterus from its inflammatory adhesions, an incision was made through the fundus and with some difficulty, on account of a caput succedaneum, from the constriction ring of the cervix, a well developed male child weighing 6½ pounds was delivered. The placenta was adherent, thrombosed in many places and apparently diseased. Another baby, which weighed 5½ pounds, was delivered a few seconds later. This placenta was not abnormally adherent or diseased. The first baby was resuscitated with considerable difficulty. The mother's appendix was postcecal, drumstick in shape, and imbedded in an inflammatory mass. In the writer's opinion the peritonitis originated in this appendix. On account of the diseased condition of the uterus a hysterectomy seemed to be indicated, but the patient was in such a dangerous condition that nothing was done except to place double ligatures on each tube in the hope of preventing future pregnancies. The abdomen was closed in tier sutures as quickly as possible. Sixteen ounces of physiological saline solution was given intravenously in each arm during the operation. The patient left the operating room in extreme shock and had a rather serious convalescence. The operative interference seemed to aggravate the peritonitis. The day following the operation the patient's temperature rose to 103 3/5 F. and continued high for ten days. She had frequent chills, excessive sweats, and a heart action that was most unfavorable. A bowel movement was not secured for four days, but peristalsis was finally reestablished, largely, the writer believed, through the effect of small doses of pituitrin administered regularly every two hours. Pus formed and gravitated to the cul-de-sac, where it was easily removed by vaginal puncture and drainage. Following this the patient improved rapidly. She left the hospital in good condition, and with two fairly healthy looking

babies on June 26. The father reported during the holidays that the mother and babies were well and thriving.

Dr. WALTER B. MOUNT called attention to a complication which was possible in a cesarean section done after a woman had been in labor a long time, where the cervix was undilated and the head was wedged in the pelvis. He had had such a case, in which pituitrin was given just as the operation was begun, and before the head was freed from the uterus had contracted so that it became necessary to enlarge the wound. It was well to keep the possibility of such an occurrence in mind in connection with the administration of pituitrin and cesarean section.

Dr. HERMANN GRAD said Dr. Conway was to be congratulated on the outcome of this most desperate case. If he had done a craniotomy the acute appendicitis would not have been discovered and relieved and the lives of the infants would not have been saved.

Spontaneous Evolution of a Transverse Presentation. Dr. WALTER B. MOUNT of Montclair, N. J., reported this case. He stated that the patient was forty-two years of age, colored, and the mother of nine children. She had been married twenty-three years and had had no miscarriages. The first six children were delivered by a midwife. The last pregnancy, five years ago, was not as comfortable as the others. The patient complained of weakness, edema of the feet, and a little vomiting. She was admitted to the hospital on March 22, 1914, in the second stage of labor and it was thought that they were dealing with a breech presentation. During the second stage of labor the bleeding became less, the placenta was not felt, the cord was prolapsed and was not pulsating; it was replaced and remained above the presenting part. The fetal heart could not be made out at any time. As the presenting part appeared it looked like a head without hair. The pains became very severe, and at 9:37 P. M. the child and placenta were delivered at once as a transverse delivery, a so-called spontaneous evolution. The cord was short, being only about 12½ inches in length. As the child was delivered the scapular region presented first.

Forceps Delivery After a Cesarean Section.—Dr. MOUNT reported this case also. He said that the patient, a large woman, thirty-one years of age, with good pelvic measurements, fell into labor at term, on August 23, 1915. At 2 P. M. the cervix was two fingers dilated, the membrane ruptured, and the presentation seemed to be vertex. At 10 P. M. the cervix was over three fingers dilated and the brow was presenting. The fundus was high and very prominent, contracting hard and frequently. The fetal heart was faintly heard. The forehead was felt to the right and in front, the position being right fronto-anterior. It seemed best to do a cesarean section. The child weighed 10 pounds 14 ounces. The patient was discharged on the thirteenth day. Two years later she became pregnant again. In the meantime she had gained in weight and during the last months of this pregnancy her urine had shown she had hypertension a few times; she also had dyspnea and tachycardia. She was delivered on January 27, 1918, at term. The position was L. O. A., and after being in labor for six hours the cervix was fully dilated and the pains had become harder. The membranes were ruptured artificially. Uterine inertia then occurred and forceps were applied. The child, weighing 11½ pounds, was rather easily delivered. There was very slight post-partum hemorrhage. Lacerations were repaired and the mother and child did well.

Dr. SAMUEL J. SCADRON said that spontaneous delivery in an oblique presentation was not a frequent occurrence, especially when the shoulder presented. About a year ago a multipara in her fifth pregnancy came into the hospital and on examination the arm of the fetus was found to be prolapsed. The cervix was soft and dilatable, admitting about three fingers. The patient was apparently not in active labor. She was ordered to bed and about two hours later, when the speaker arrived and was washing preparatory to examining her, she was seized with a strong uterine contraction, and when she was examined the buttocks of the child presented, with the arm remaining prolapsed through the vagina. With the next uterine contraction the patient delivered herself spontaneously of a still

birth which was full term. It seemed to him that in his case the shoulder of the child was driven down into the pelvis and became fixed under the symphysis, while the breech, trunk, and limbs were forced past this part. The case reported seemed to him to be a birth with the body doubled up, for in a case of spontaneous evolution the arm was invariably prolapsed beforehand.

Dr. MOUNT, in closing, said he had looked up the literature on transverse presentations and did not find it very clear in reference to terminology. He did not know that this case should be called one of spontaneous evolution, but that was what De Lee called it and that was why he had taken this terminology. Criticism might be directed against doing a cesarean section in a brow presentation. There were two factors which influenced him to perform a cesarean section. The one was that he had seen two cases of brow presentation delivered by forceps with disastrous results to the baby and injury to the mother in one instance and in the other instance the baby's head was badly treated. The other reason was that the uterus was contracting rather hard and there was danger of hemorrhage or perhaps of rupture of the uterus.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting Wednesday, February 27, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

X-Ray in Fractures.—Dr. HENRY K. PANCOAST in this demonstration, with lantern demonstration, said that notwithstanding the fact that the diagnosis of fractures was one of the oldest procedures of roentgenology, improvements in technique were still being made. He thought it probable that after the war the fluoroscope would be used to a larger extent in the correction of deformities in fractures. It should not, however, be depended upon for diagnosis. Great care would have to be observed in protection against burns. The diagnosis of fractures of the skull and spine he said had been improved to a very considerable extent in recent years. In the diagnosis of spinal fractures two views of the spine should be made whenever possible. Many crushing injuries of the vertebral bodies would escape notice unless examined laterally, as an anteroposterior view frequently failed to show a fracture.

Treatment of Fractures of the Jaws by Means of Dental Appliances.—Dr. GEORGE M. DORRANCE spoke upon this subject and presented various forms of appliances described.

Correction of Deformity in Fractures.—Dr. T. TURNER THOMAS regarded as of most importance in the correction of fracture deformity the knowledge of the force producing the fracture. The theory of muscle pull, prevailing for many years, seemed to be yielding its place to the theory of the fracturing force as the cause of the deformity. Positive statements against the former or in favor of the latter, however, were yet wanting. The great difficulty he felt was encountered in accounting for the force which nearly always produced the same deformity in each of the common fractures and dislocations. The tendency was to assume that the character of the fracturing force varied widely. Were this true, however, and the deformity due to the fracturing force, the deformity would vary with the force applied. What kind of a force, he questioned, could essentially always produce the same deformity in fracture of the clavicle, dislocation of the shoulder, fracture of the surgical neck of the humerus, supracondylar fracture of the humerus, dislocation of the elbow, and Colles' fracture. The fall upon the hand he believed was the only force which could meet this condition. This was now accepted for practically all Colles' fractures and must eventually be accepted for nearly all the fractures and dislocations of the upper extremity, or the idea that their typical deformities were due to the fracturing force must be abandoned. When the fracturing force was known the deformities would be reduced by dragging the displaced fragment back into its normal place through the same path by which it was driven out, but in the opposite direction, just as

Allis did with dislocations of the hip joint. This principle had been applied by Dr. Thomas with much satisfaction in a group of fractures and dislocations.

Treatment of Fractures by the Orthopedist.—Dr. HARRY HUDSON in a paper on this subject agreed with Dr. Thomas that the mechanical cause of fractures of malposition was the blow and not the muscle pull; the deformity was merely retained by the muscle and not caused by it. He was inclined to divide the life history of a fracture into three periods: (1) The beginning of the condition, extending during the time of the acute symptoms and possibly to the beginning of the formation of callus; (2) the interval from this time to the firm fixation of bone by fibrous or bony ankylosis; (3) the time which he had been pleased to relegate to the orthopedic surgeon, unless further operative treatment was required. It was his opinion that in the first period too early effort was frequently made to reduce the fracture. There was at this time more or less bruising, muscle spasm, nervousness, etc., and naturally there would be failure to obtain the co-operation of the patient. Such difficulties might be avoided; and the dangers of a short wait, he believed, were not so great as often supposed. He was thoroughly convinced of the value of rest for the patient for a short time before undertaking the manipulations of reduction. During the period of waiting the surgeon should acquire a full knowledge of the condition and undertake the reduction with the same confidence in his methods as if he were doing a surgical operation; otherwise, he would not have the confidence of the patient often essential. In the setting of a fracture too often the surgeon had in mind some classical condition and looked for a classical method of reduction. If he would realize that something was to be gained by manipulations, molding, slow, intensive force, he would be more successful than in an effort to follow classical methods. After the setting of the fracture Dr. Hudson used with great satisfaction the plaster-of-Paris splint, easily molded to meet the indication. He believed thoroughly in massage and means designed to preserve the blood supply of the injured limb during healing; feeling that they decrease the long third period sometimes seen in the treatment of fractures.

Fractures in the Newborn.—Dr. EDWARD P. DAVIS said that fractures in the newborn might be divided into complete and partial. It was to the credit of medical science that complete fracture in the newborn is of rare occurrence. Pelvimetry and, in proper cases, cesarean section, had ruled out version in contracted pelvis, responsible for many fractures. Incomplete fractures, therefore, were as a rule those to be dealt with. In the cranium distinction must be recognized between the effects of birth pressure without fracture, and fracture. Depressed fracture of the cranium might be immediately treated by making an incision over the point of depression and raising the bone. This was followed by cessation of symptoms. Other fractures of the cranium included those of the base, produced purposely by craniotomy, and those arising in difficult extraction when the operator had misjudged the proportionate size of the child to the pelvis and attempted to drag too large a child through the pelvis. Fractures of the extremities in the newborn were almost always of the upper extremities. In dealing with fractures in the newborn the forces of development should be considered and the mistake not made of diagnosing fracture where failure in development of the fetal skeleton had before labor predisposed to fracture. Attention was called to the possibility of fracture in the newborn subjecting the attending physician to criticism and possibly to medicolegal action. Unless the fracture had occurred through very marked neglect in the effort to ascertain the size of the maternal pelvis, or failure to diagnose engagement, or other fault in management of the labor, it was to be recognized that in some cases injury to the skeleton was inevitable were delivery to be effected with preservation of the life of the mother and child. At the present time, however, fracture in the newborn had become exceedingly rare.

Dr. RICHARD C. NORRIS referred to Dr. Davis' statement that while fractures in the newborn had been greatly lessened there was still a group to be seen in spite of the obstetrician's skill. In all cases in which

he suspected fracture it was his rule not to depend upon physical examination but to resort to the use of the x-ray. This was especially applicable in suspected fracture of the clavicle. Fracture of the humerus would sometimes occur in extending the arms in the breech case. In cases in which after a difficult labor there was the slightest sign of deformity an x-ray was taken. In the medicolegal aspects it was to be remembered that the most skillful man would sometimes have fractures and that there were changes in the bones in some infants predisposing to fracture. Any physician on the stand as a witness in a damage suit should be most cautious in expression of his opinion that in any particular case the injury was due to lack of knowledge or precaution.

Dr. GEORGE P. MÜLLER, referring to Dr. Dorrance's statement that many fractures of the lower jaw were not reduced, said that he had been able to make such reduction but had difficulty in keeping them reduced. It was, therefore, his custom to send them to Dr. Dorrance who had the apparatus for maintaining reduction. Dr. Müller agreed with Dr. Hudson upon the advantage in not at once reducing fractures. While early reduction had previously been his custom he now thought it better to wait for 24 or even 48 hours, and then with full knowledge of the case proceed with as much care as in the consideration of duodenal ulcer. Emphasis was placed upon the importance of massage and exercise in the after-treatment.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

LOCALISATION ET EXTRACTION DES PROJECTILES. Par L. OMBREDANNE ET R. LEDOUX-LEBARD. 305 pages. Illustrated. Price, 4 fr. Published by Masson et Cie., Paris.

EVOLUTION DE LA PLAIE DE GUERRE. Par A. POLICARD. 189 pages. Illustrated. Price, 4 fr. Published by Masson et Cie., Paris.

TEN CASES OF THYROID DISEASE.

By S. P. BEEBE, Ph.D., M.D.,
NEW YORK.

It happens not infrequently that general principles of therapeutics are best presented by illustrative cases. The young medical practitioner, as a matter of fact, soon learns that he is obliged to treat a patient, and not infrequently the patient's relatives and friends, rather than a classic well-defined disorder in a mechanism of uniform construction and invariable uniform response. By experience he learns the numerous exceptions to the rule and appreciates the marvelous complexities of the mechanism which he tries to modify by the various agencies that form the weapons of present day therapeutics. Actual cases, therefore, not only permit generalization, but they serve to show the limitations and exceptions to sweeping conclusions. It is the purpose of the writer in presenting the ten cases of thyroid disease to illustrate some of the conditions that demand relief, and to describe in some detail the methods that have been followed in their treatment. In the writer's experience no one method is suitable for all cases and the good effects as well as the limitations of methods now in common use will best be presented with actual cases to serve as a text.

CASE I.—A young school girl, aged thirteen years, sought treatment because of a beginning enlargement in the neck. Had always been in good health except for the children's diseases, measles and chicken pox, which she had had in mild form at ten years of age, and an attack of acute tonsillitis lasting ten days, six months previous to coming under observation. The recovery from the acute infection had been slow, she had passed a period of six weeks in the Berkshire Hill region during the convalescent period, but during the last three months had been in apparent good health. Patient was above normal weight for her age, had ruddy cheeks, was well developed, and menstruation had begun at the twelfth year. Appetite excellent, sleep good, bowels somewhat constipated requiring an occasional cathartic, no headaches, rather quick and jerky in her movements, tires easily on physical exertion. Thyroid gland well developed, first enlargement noted during convalescence from tonsillitis and had been progressively increasing until at present both lobes and isthmus involved and five to six times the normal size. The tonsils were found markedly enlarged with deep crypts and they, as well as the mucous membrane of the pharynx congested and inflamed. Heart overacting with characteristic thyroid thump, no murmurs, pulse rate 95 after five minutes' rest. No exophthalmos. Well developed tremor. Skin sensitive, marked dermatographia. Tongue covered with white fur with bright red edges. Patient expresses herself as feeling fine. Patient had had no joint trouble at the time of the acute tonsil infection and the heart showed no valvular lesions.

This patient was selected as No. 1 of this list because her condition is fairly typical of a large number of cases that develop at about this age, and in a large percentage of cases have the history of an acute nose and throat infection preceding the development of the gland. The writer has discussed the relation of nose and throat infections to the development of goiter in a previous publication, but approximately 40 per cent. of the cases that have come under his observation have shown such coincidence.

The parents of this patient were above the usual intelligence and were not satisfied with the judgment pronounced by a previous consultant that the enlargement was of no significance and would disappear as the child grew older. This pernicious advice is still too commonly given and, in the writer's judgment, was equalled by the subsequent advice from another source that operative removal of the gland offered the only hope of relief. At this age and in this type of gland both lines of advice are not a credit to the medical profession. The treatment applied to this patient is not difficult to administer and has proven effective in such a large number of this type of patient that it is believed a legitimate confidence may be had in it.

Treatment was as follows: First in regard to diet. Tea, coffee, and all stimulants are denied. No meat or flesh foods of any type were permitted. No meat soups or soups made from a meat stock are allowed. The bowel conditions must receive careful consideration. It is usual to find a condition of constipation. Most patients feel that if the bowels move as often as once in two days sufficient action is present. This patient was permitted to continue in school work, but was protected from all unnecessary physical exertion. All physical training in school was stopped. Long hours in bed were required. Few visitors, little excitement, no picture shows, entertainments, etc., were permitted for four months.

The medicines prescribed to this patient were as follows:

1. The official mixture of rhubarb and soda in $\bar{5}$ ii doses diluted with water after each meal.
2. Syrup of ferrous iodide in fifteen drop doses after meals.
3. The nose and throat were sprayed several times daily with the following solution: Menthol, gr. XXX; Eucalyptol, $\bar{5}$ i; Petrolatum q.s. ad $\bar{5}$ ii.
4. A cold compress applied to the neck each night for the first month.
5. The patient had a warm spray bath each morning ending with a cold shower.

The above outlined program was continued without change or modification for a period of three months. The patient had improved in every respect. The gland was about one-half the size it was at the beginning of treatment, and the heart quieter. The tremor observed at the beginning of treatment was barely noticeable. There had been no change in weight.

At this time the only change in the medicine admin-

istered was to discontinue the ferrous iodide and to substitute potassium iodide in one grain doses after each meal. Six treatments at weekly intervals with the x-ray were now added to the therapeutic measures. Two months later the tonsils were enucleated.

At the end of six months the patient was found to have no perceptible thyroid enlargement but the isthmus was still felt as a band crossing the trachea at the fourth cartilage a little broader and thicker than usual. The patient was permitted to resume normal activity gradually but no change in diet was permitted except to eat chicken twice each week. Iodin was given in the form of potassium iodide, one grain doses after meals for periods of two weeks during each month. The bowel conditions were controlled with a diet of fruit and vegetables and by appropriate exercise. At the present time, three years after beginning of the disease, the patient is in excellent health with no physical evidence of thyroid disease. This patient showed a type of thyroid enlargement that is common in this section of the country. The vast majority of these cases can be controlled by the simple medical measures enumerated and no more need to have a portion of the gland removed by surgical operation than do they need to have a breast removed because some of the gland lobules show swelling and tenderness during the menstrual period.

CASE II.—Patient was a young woman of 17 years, with a history of palpitation for the last three months with the recent development of a tremor, loss of weight, and lack of sleep. She had had no previous illness or infection to which the development of the condition could be attributed. She was five feet, three inches in height, weight 104 pounds, had a slight exophthalmos, a well developed, characteristic tremor; the heart was dilated with a well marked functional systolic murmur heard over the apex and base, the skin was very sensitive and she perspired freely; appetite excellent, always hungry, requiring twice the food of her older sister. The bowels acted freely two to three times daily and the abdomen was not sensitive but showed in the abdominal aorta and its larger branches the water hammer thump so frequently found in hyperthyroidism. The menstrual periods were regular but scanty. The thyroid was uniformly enlarged, both lobes and isthmus involved, with a marked thrill. She became breathless on slight exertion. Patient had been in bed for three weeks to prepare for operation previous to her first visit.

This patient presented a well marked characteristic condition of hyperthyroidism which had followed although perhaps not related to a severe fright she had experienced five months before.

Treatment.—Diet, the same as noted for first patient, a rigid meat-free diet, which means exclusion of all types of flesh food, fish, fowl, or beast, and of soups prepared from them. No tea, coffee, or stimulants of any sort. Cereals, eggs, milk, fruit, and cooked vegetables in abundance are permitted. Food up to the demands of the unusual appetite was not only permitted but urged.

All unnecessary activities were stopped. Patient must lie down one hour each forenoon and two hours each afternoon, with ice bag applied to neck. In bed at nine o'clock each night, arising not earlier than eight in the morning. Excitement, visitors, and unnecessary physical exertion prohibited.

Patient came to office every second day for an injection of antithyroid serum. Injections were begun with two minims, and gradually increasing to ten minims. No further medication was given during the first six weeks. The heart action became much quieter, the headaches were entirely relieved, the patient slept soundly every night, and the gland diminished rapidly in size. After six weeks of serum treatment, injections were made at longer intervals and were continued altogether for a period of four months, during which time the patient had 34 injections.

Two months after the beginning of treatment the patient was given one three-grain capsule of the neutral hydrobromide of quinine twice daily.

Three months after the first visit patient resumed normal activity and returned to work. At that time she had gained weight from 104 to 118 pounds. One year after her first visit she weighed 132 pounds, was

in excellent health, with no evidence whatsoever of her former disease. Blood pressure was at that time 118, heart normal in every respect, and no enlargement of the thyroid could be seen or palpated. The type of patient described is frequently subjected to operation. In the writer's opinion, such a method of treatment is unnecessary for the majority, although as a rule they withstand the operation, but they are readily controlled by medical means.

CASE III.—A young woman, college student, 22 years of age, who was referred by her family physician because she was believed to have goiter, which might be responsible for fainting spells noted on several occasions during the last two months. Her family history was interesting, as her mother had had a so-called simple goiter for many years. In the family were three other daughters, all of whom had goiter.

The patient had no exophthalmos; she had suffered during the last three months with severe headaches. Her bowels were constipated, and she frequently was nauseated. Her heart was irregular and markedly over-active, with a rough systolic murmur at the apex and with a rate of 120 after rest. She had had repeated attacks of tonsillitis during the last two years. At the time of her examination she had inflamed tonsils, with a congested pharynx, and the cervical glands draining the tonsils were enlarged and tender. She had lost weight, eight pounds, during the last two months. Her menstrual periods had been interrupted during that time also. A marked brownish pigmentation was well shown over the neck and cheeks and about the borders of the hair. She was physically weak, with a well-marked tremor, but had continued her college and social activities until two days previous to her first examination. The thyroid gland was four or five times its normal size, constituting a large goiter, but the isthmus was not much enlarged. The gland was smooth, fairly firm, somewhat tender, but without thrill or bruit. The right lobe was one-third larger than the left. She had a well-marked area of dullness over the thymus region. She had consulted a physician because on four occasions within the last month she had fainted during excitement, the last occasion taking place on a public street near her home, to which she was removed by a policeman who had observed the occurrence. An x-ray picture of her chest revealed the presence of an enlarged thymus gland.

Treatment.—Patient was kept continuously in bed for four weeks, and was allowed to have visitors only twice each week. The meat-free diet previously described was followed. For her bowel conditions the following mixture was given in teaspoonful doses after meals.

R Rhei pulvis	5ii
Sod. bicarb.	5iv
Fl. ext. cascara sagrada (aromat.)..	5iii
Aq. menth. pip.	q.s. ad 5vi

Her throat was sprayed several times daily with the prescription previously given. After one week's rest in bed the serum injections were begun with a dose of two minims. The injections were given at two-day intervals and the dose gradually increased to 12 minims. In one month she had very markedly improved. Her gland was about one-half the size it had been previously and she was without headaches or inflamed throat and tonsils. The pulse rate was 80 and regular when quiet, but her heart was still sensitive to exercise or excitement. She was allowed to go about some, but not to engage in social activity. The diet and medical measures were continued for two months longer. During the second month it had been observed that her muscular strength did not improve as desired and her tremor was still pronounced. At the beginning of the third month she was accordingly given one grain of potassium iodide three times daily. In a very few days the tremor was almost completely abolished and her strength improved rapidly. The writer has observed small doses of iodine to be of the greatest service in the conditions mentioned.

At the end of the third month of treatment her thyroid gland was about one-third its original size; in fact, it scarcely annoyed the patient by its size. The heart was slow and regular and she was able to stand ordinary activity without undue fatigue. She had gained

15 pounds in weight. Without my approval she now decided to drop treatment and go to the country for the summer.

The patient was not seen again for four and one-half months, during which time she had had no treatment and had lived an active social life in a popular summer colony. She cut the period short of the full term because of renewed trouble with her heart and a beginning exophthalmos of the right eye. Her gland and heart were now nearly as prominent features as before, and tremor was again present and headaches were beginning. Treatment was resumed as before, except that the patient was not put to bed. Diet, rest, bowel treatment, iodine, and serum treatment were begun. Three weeks later her tonsils were enucleated. In six weeks from the resumption of treatment she was given eight x-ray treatments at weekly intervals over the thyroid and thymus region. Following this period all treatment except diet and serum injections was discontinued. Potassium iodide was continued at intervals in the small doses described. The second period of treatment lasted six months. Altogether she had 58 serum injections. Four months after all treatment was stopped she was in excellent physical condition, having gained 30 pounds since the first examination. She had no tremor, no visible or palpable thyroid, her heart was normal, skin clear and pink, no menstrual disturbance, and no gastrointestinal difficulty. One year later she married and has now had two children. There has been no return of her former condition and no evidence of any abnormal function of her thyroid gland. During her pregnancy she continued to take one grain of potassium iodide twice daily every other day.

Some years ago the writer had occasion to advise a mother who on her first pregnancy had given birth at term to a fetus that had a malformation of the thyroid apparatus and did not live. The second pregnancy produced a hypothyroid child, almost a cretin. During the third and fourth pregnancies small doses of iodine were given and she gave birth to healthy children.

CASE IV.—A young woman, school teacher, 26 years old, with a history of goiter since her sixteenth year. She had been in good health until two years previous to her first visit. She then suffered a so-called nervous breakdown which caused her to take a rest of several months. Nervous breakdown is a term that is too frequently used to cloak a real hyperthyroidism that has escaped diagnosis. Since the period of her previous illness the patient had never been well, she fluctuated in weight, noted that her gland had increased a great deal in size, that her eyes were becoming prominent and that her loss of weight during the previous four months had been a rapid one. She was still at work, but found it very difficult to continue her activities.

Examination showed patient to be very thin; she had lost forty pounds in weight during the last six months (weight, 106 pounds); was very nervous, with a violent tremor of the whole body. She had a very pronounced exophthalmos, and the conjunctiva was inflamed. She was perspiring freely and the skin reacted markedly to the least irritation. On the sides of the neck and over the upper portion of the chest the skin showed a dark dirty brown pigmentation. She had a large nodular hard goiter involving all portions of the gland, the right lobe being much the larger. The gland showed a distinct expansile pulsation, thrill and bruit. Her heart was dilated, rapid, 130 to 150; irregular loud systolic blow at the apex and base and in the large vessels. The abdominal aorta beat violently with the characteristic water-hammer pulse. Blood pressure of 145 mm. On small exertion or excitement the heart became more irregular, increased its rate, and was very annoying to the patient.

Subjectively she had frequent headaches, occasional nausea and vomiting. She did not sleep well, was constantly annoyed by most exciting dreams. Her menstrual periods had not appeared during the last six months. She was very much depressed mentally.

From her history it became evident that her thyroid gland had been over-active for several years. She had

a severe, typical case of exophthalmic goiter, and if she had had the good fortune to have had an accurate diagnosis and appropriate treatment several years previously, the present unfortunate severe condition would have been entirely prevented. A large percentage of the so-called simple goiters in young women in this section of the country have in them all the potentialities of the case in point.

Treatment.—Complete rest for first three months. After that patient was allowed a mild degree of activity. Meat- and stimulant-free diet rigidly enforced continuously. Serum injections were begun and continued in the manner previously described, the injections being made every second day. Two months after beginning serum injections the syrup of ferrous iodide in ten-drop doses after meals was begun. This program was continued for a period of six months. The patient improved a great deal; the pulse rate fell to below 100; she had no headache, but was occasionally sleepless; she gained in strength, but did not stand exertion well. Her gland had reduced in size so much that her neck was two inches less in circumference. She had gained 24 pounds in weight. She wished to return to work at once, as her financial condition did not permit her to continue under the regime advised. She still had a large right lobe and was not in condition to return to the fatigue and excitement of school teaching. She agreed to operation. She entered the hospital with the understanding that she was to have a period of special treatment, and that if it should be found advisable the operation was to be performed. While continuing the serum injections she was given a hypodermic of salt solution each morning at 8:00 A.M. and one-half hour later some oxygen inhalations. Her entrance to the hospital was the cause of added excitement to her at first, but after two weeks she had become acquainted and accustomed to the routine.

On the morning determined for operation she was given $\frac{1}{4}$ grain of morphine and $\frac{1}{150}$ of atropine instead of the regular salt solution. One-half hour later she took the gas anesthesia quietly and without added excitement. The subsequent excision of the right lobe and isthmus was readily accomplished. Her convalescence was a slow one. She remained in the hospital four weeks after operation. The heart became gradually stronger. She gained in weight and progressed favorably in all respects. The operation was made in September, and in January she resumed teaching. She was in fair condition, but not well, and was cautioned to continue the diet, serum, and as much rest as possible. However, she became careless about these matters and in March showed a well-marked exacerbation of the disease, with the left lobe increased in size. The rigid program instituted at the beginning was again advised and to this she agreed, except that she was allowed to teach two hours daily. Improvement was rapid; the injections of serum were made at longer intervals; one grain of potassium iodide and five grains of the neutral hydrobromide of quinine were given twice daily for a period of five months. Her whole treatment lasted a year and a half, and it was continued for one year after operation. She had altogether 140 serum injections. She gained in weight 46 pounds and was in excellent good health. She was seen recently, six years after treatment began, and has no evidence of thyroid disease that can be discovered. She weighs 53 pounds more than when first seen; has all the appearance and earmarks of abundant good health.

I believe the long period of treatment after operation was essential to her recovery, and feel confident that her treatment previous to operation made this a feasible and safe procedure.

CASE V.—In the case of this patient is presented a somewhat sharp contrast to the one just preceding and one which shows how operation should not be done. The patient was a young woman, 22 years of age, with a history of goiter for six months. She had a typical picture of mild hyperthyroidism without exophthalmos. She was a stenographer, and in spite of loss in weight of 12 pounds during the last two months and increasing nervousness had kept at work. Her gland was increased to twice its normal size, both lobes and the isthmus being involved. She had a well-marked tremor,

pulse rate of 110 to 120, had a slight pigmentation of the skin, and was blessed with a good appetite and no digestive disturbance. She had a history of repeated attacks of sore throat the preceding winter. She was advised to put herself under a regime of rest and serum treatment, to which she could agree only in part, stating that she would not give up her daily work as a stenographer. After three weeks' treatment she announced that she was anxious and determined to have an operation, as she could not interfere with her work to come for serum treatment, and furthermore expected to be married and wished to be rid of the bunch in her neck as quickly as possible. She had consulted a surgeon and seemed to be a safe operative risk. Permission for operation was given. She entered one of the large hospitals the night before operation. No special attention or care was given to her, and in the hospital in question operation is a business-like proceeding with no attempt at camouflage. She spent a sleepless night and became more nervous and agitated as the hour for operation approached. She was taken to the operating room and given a straight gas-ether anesthesia by one of the internes. The surgeon was somewhat delayed in his preparations so that the patient was under the anesthetic 20 minutes before operation was begun. The patient's pulse at this time had a rate of 160. The operation did not proceed smoothly or rapidly. On one occasion a clamp slipped and a small hemorrhage ensued. Finally the right lobe and isthmus were removed, the wound closed, and the patient taken down stairs, where she died twenty minutes later.

This case is cited to show how operations of this character should not be done, and to emphasize the necessity of having all the details of the technique under control from the time the patient enters the hospital until discharged. The hyperthyroid case is exceedingly sensitive and even a mild case cannot be roughly handled with impunity.

CASE VI.—Patient was a woman, 47 years of age, who had undoubtedly had goiter for many years. Her own knowledge of the condition dated back two years. At that time she had consulted a physician for nervousness. No diagnosis had been made, but she had been given a simple tonic. Eight months previously she had consulted a specialist, who diagnosed the condition and advised x-ray and rest. She had four treatments, but because they excited her so much she had stopped them and had gone to her country home for a complete rest. After four months' quiet she had not improved and decided on further consultation. She was found to have a fairly typical case of severe, long-standing Graves' disease. She had lost weight during the last five years and had a history of always being nervous, but of being animated and constantly active. She now presented a marked exophthalmos, a small, very hard goiter involving both lobes and isthmus, a dilated, irregular, rapid, painful heart, rate of which varied from 120 to 160, a blood pressure of 155, a congested, irritated throat, great muscular weakness, with well developed tremor, frequent severe headaches, a poor appetite and constipation, very troublesome insomnia, with such periods of sleep as she did have disturbed by most vivid harrowing dreams, often causing her to cry out and to toss restlessly from side to side. She was, at times, almost maniacal and occasionally had delusions of time and place. A further disturbing factor was her menstrual periods, which occurred irregularly and were characterized by great mental depression, scanty flow, increase of insomnia, and complete loss of appetite. She had a slight temperature of 99° to 99.5° not infrequently. She had led an active social life until the last few months, and had undoubtedly needed treatment years before.

Treatment.—Absolute quiet and complete rest, meat- and stimulant-free diet; bromide and occasionally veronal were given to induce sleep. Serum injections were begun. Ice-bag to heart and over gland. Hydrotherapy in the form of a warm bath was sometimes effective in inducing sleep. Enemas and a mixture of rhubarb and soda kept the bowels active. The improvement was slow and gradual, but the heart quieted to a

rate of 85 to 95; was no longer annoying to the patient; the exophthalmos was much less noticeable; the insomnia was still troublesome at times, and four months from the beginning of treatment the conditions were progressing satisfactorily, with the exception of occasional attacks of paroxysmal tachycardia that appeared without warning and would last for periods varying from one hour to seven or eight hours. The most effective measure in controlling these attacks was an intravenous injection of morphine, $\frac{1}{4}$ grain, and digalen, 15 minims. They caused most acute distress until controlled. There had been only one menstrual period during this time, which had not greatly annoyed the patient. Shortly after the fifth month had passed and at a time when conditions were particularly favorable the patient suddenly, during a period of 48 hours, developed an acute excitation, was entirely sleepless for two days, exhibited delusions of time and place, could no longer recognize her attendants, and in spite of hypnotics was at times so violent as to require restraint. There appeared a slight menstrual flow on the third day, but the excitable delusional condition lasted for three days longer. A serum injection was due on the third day of the menstrual flow and was given. It was followed by a period of quiet sleep lasting nearly 24 hours, from which the patient awoke with her mind clear but with a complete memory blank of the events during the preceding week. She was very much weakened by this experience, but her pulse rate, gland, exophthalmos, and tremor had not been noticeably disturbed except during its continuance. The patient was removed to a nearby coast resort and the previous treatment continued. Here she gained rapidly and all phases of her condition were satisfactory. The attacks of tachycardia no longer appeared; sleep, appetite, and gain in weight were indicative of steady, favorable progress. It was decided that she should return home, but she wished to remain in New York City for two weeks. Ten weeks had now passed since the previous menstrual period. Now again there was a stormy onset lasting about 36 hours, followed by the appearance of a menstrual flow which on this occasion was profuse, in contrast to the former ones, which had been scanty. All the acute mental manifestations accompanied this period. Because of her previous good progress the serum injections were less frequent at this time, but the storm was ended by a long period of sleep; 36 hours of 48 were passed in quiet, restful sleep, without hypnotics. When she awoke she had no memory of preceding events and only when several days had passed was she clearly oriented. Two neurologists and three gynecologists were called in consultation at this time, but could offer no helpful suggestions. During the next three months this patient improved rapidly. She had one menstrual period during this time which caused no disturbance. Her gland became almost normal in size; she was given small doses of potassium iodide; her tremor was scarcely noticeable; she was beginning again to take up the thread of her normal activities. Her pulse rate when quiet was 75, but on excitement would reach 90. She slept well and was making excellent progress. It was now ten months since her treatment was first begun. She had had 88 serum injections, had gained 25 pounds in weight, and was entirely free of the distressing symptoms of the disease.

Now again a period of one week of most acute melancholia and insomnia ushered in a menstrual period which in character was like those already described. During this period she had on one occasion become uncovered and exposed to a chill wind for two hours. She developed a mild acute tonsillitis, which was controlled fairly promptly. Two days after this had subsided she developed a temperature of 101°; the cervical lymph glands were swollen, the tonsils were swollen but not painful. Throat cultures were negative for Klebs-Loeffler; blood counts showed a mild hyperlymphocytosis; blood cultures, at first negative, three days later showed a positive culture of *Streptococcus viridans*. The heart valves became involved shortly afterward; the temperature continued to run between 99° and 101°. In ten days from the time the infection was first manifested the patient died.

This patient showed a combination of conditions quite out of the ordinary. In five fatal cases oc-

curing during the last eight years the writer has had the same type of blood infection, and in each case the patient has not survived longer than two weeks after its first appearance. This is a much sharper and shorter infection than is usually noted with this organism and may denote a special susceptibility in these cases.

Since this first case of extremely toxic menstrual period complicating Graves' disease, the writer has seen three others of equal severity. They were all in women over forty years of age. In the second the ovaries were removed by vaginal section. The case continued to make a complete recovery and is now well. In the two others the condition was controlled by active treatment of the lower pelvis with x-ray. While somewhat slower in operation this procedure has been found equally effective. In the operated case the ovaries were found to have many small cysts.

The menstrual function is often disturbed in hyperthyroidism, in most cases the gland becomes more swollen, all the symptoms of the disease are more pronounced during this time, but such extremely toxic periods are quite uncommon. It is, of course, not unusual to find a complete cessation of the periods during the more active stages of the disease.

CASE VI.—A young woman, 24 years of age; first seen eighteen months after a second operation for hyperthyroidism. She had had goiter since her sixteenth year, but had not been troubled much with it until two years ago. At that time she had consulted a surgeon, who advised operation. This was done in two stages. The right superior thyroid vessels were ligated under local anesthesia. Four months later, after complete rest during that period, the major portion of the right lobe and isthmus were removed under a general anesthetic. The patient had felt better after the second operation and gained in weight. She had noted, however, that during the last few months the left lobe of the gland was rapidly growing in size. All of the old symptoms had returned in greater intensity than ever before, so that she now expressed herself as being worse off than before the operation.

She had all the typical manifestations of a text-book case of exophthalmic goiter. The heart tremor and exophthalmos symptoms formed an excellent demonstration. The scars of the former operation were very pronounced and not a particularly good recommendation of the artistic skill of the operator. Both lobes of the gland were much enlarged, though the shape of the right lobe was much distorted.

Heart dilated; irregular loud systolic blow at apex and base and over the large vessels. Blood pressure 140. Violent forcible abdominal pulsation. Heart rate 120. Skin markedly pigmented on sides of neck, cheeks, and over upper part of chest. Patient perspired very freely and skin was very sensitive to irritation. The gland showed expansile pulsation and a very unusual thrill and bruit on the operated side. There was great muscular weakness, characteristic tremor, and pronounced physical unrest. The lids could scarcely cover the eyes because of the exophthalmos.

The throat was congested, the voice weak and husky. The tongue was not coated and the patient had a most voracious appetite, good digestion, and satisfactory bowel conditions. She had no trouble with sleep and did not usually dream. The physical signs of the disease could not have been better shown, but the mental and emotional disturbance was comparatively mild.

Treatment.—This patient was not able to stop work, but did not have an exacting occupation. Her condition of recurrence was typical of that seen many times by the writer. The meat- and stimulant-free diet previously described was required, together with as much rest as her occupation would permit. For four months she had no further medication than thyroid antiserum. She was then given in addition one grain of potassium

iodide three times daily, which was continued for six months. The serum injections were continued for one year and one month, during the latter part of the time at gradually increasing intervals. She had altogether 127 serum injections, and now, two years since treatment was discontinued, is and has been perfectly well and free of all manifestations of thyroid disease except the scars in her neck from the previous operation.

CASE VIII.—A man, 32 years of age, had not noted goiter or exophthalmos until six months ago. He had then sought medical advice, with the result that x-ray treatment was advised. During the succeeding ten weeks the patient had a treatment each week. It was not possible to learn the type of machine or tube used for this purpose, but the exposed area on the neck and chest still retained a brownish pigmentation and was dry, scaly, and without hair, showing that the exposures had been intense enough to cause a mild superficial burn. Patient did not improve and had ceased all treatment during the last six months.

Patient had a very pronounced exophthalmos and a mild conjunctivitis. His tremor was so severe that he could hardly stand. It was quite impossible for him to write or to use his hands except for the coarsest movements. The knee-jerks were much exaggerated. His thyroid was low down in the neck, firm, about twice the normal size, the enlargement involving both lobes and isthmus. He had constant choking sensations and the gland was tender. His throat was red and dry, but the tonsils were not enlarged. He had a constant cough and his voice was hoarse and weak. He had a good appetite, but was very much troubled with constipation. His tongue was heavily coated and breath foul. He complained bitterly of gas in the stomach, with occasional nausea and vomiting. He did not sleep well, three to four hours' broken sleep each night. The heart was overactive, with a rough systolic murmur, and was pounding the chest with a heaving impulse that shook the examining table. The abdominal pulsation was especially well pronounced. The patient complained of pain in the heart. Blood pressure 130 rate 110 after ten minutes' rest. The skin was sensitive to slight irritation, and the skin of the face, neck, upper chest, hands, and wrists was a bright red, almost erythematous in appearance.

A further interesting feature of this case and one which is important in both etiology and treatment is found in his dietary and personal habits. This man had been drinking six to eight cups of strong coffee every day. He ate practically no fruit and very little vegetables. Meat, meat soups, smoked fish, canned fish, and salt fish, with a little bread and pastry, had been his diet for a long period. In addition he smoked two to three packages of cheap cigarettes each day.

It will be noted that in treating the cases already described, rigid exclusion of the kind of a dietary which this patient had been practising has been one of the fundamentals. It has been observed by many men that dietary conditions have an important bearing in both etiology and treatment. Watson has found that rats fed on a meat diet show thyroid hyperplasia. The relation of toxins from the intestinal tract to the origin and maintenance of hyperthyroidism has been emphasized by many writers. W. H. Thomson was one of the first to see this point, and the experimental work of McCarrison leaves no doubt of its importance. Arbuthnot Lane, Hertoghe, Ebstein, Bate, Hemmeter, have all pointed out the intimate relation between disordered intestinal function and thyroid disease based on clinical observation. It would seem that eventually the truth must penetrate that in dealing with thyroid hyperfunction we must consider the whole status of the individual and not be content with a single line of attack.

The case cited above seems to have been a fine experiment in thyroid stimulation. Because of the general weakness from the disease thyroid patients frequently

overindulge in coffee and complain bitterly when its stimulating effects are denied to them.

Treatment.—The obvious treatment was followed. Tea, coffee, and all stimulants were stopped at once. A rigid meat-free diet, with three oranges daily and a fair quantity of vegetables was prescribed. This was a dietary revolution for the patient in question. Patient reduced the smoking to six cigarettes daily. The mixture of rhubarb, soda, and cascara was prescribed with a daily enema of salt solution to keep the bowels in condition. One grain of potassium iodide was given three times daily. This patient could not get as complete rest as desired, but he spent from 7 P.M. to 5 A.M. in bed each day. All physical exertion requiring effort was stopped.

In two weeks an entirely different picture was presented. The heart was much quieter, the rate being now 80 to 90. The tremor had disappeared almost entirely. The patient slept well. His appetite and bowel conditions were good. The thyroid could scarcely be palpated and was no longer tender. The exophthalmos was much reduced. The patient had no headache.

The treatment as outlined was continued for five months, at which time the patient was well and had no evidence of thyroid disease. He had become accustomed to the new dietary and was now glad to continue it. He was cautioned about his mode of life and came in for examination once in two months. He was last seen one year ago, three years after treatment was begun, and was in excellent health.

Just how the x-ray could be effective in the treatment of this patient when no attention was paid to such obvious etiologic factors as are shown in the history of this case is not apparent. There is danger in dealing with these cases from a one-sided standpoint or a pet theory to the neglect of obvious fundamental conditions of common-sense treatment.

CASE IX.—This case is cited because the patient shows a type of gland which is quite as common as those previously described, and yet the patients do not often seek medical advice until the symptoms produced by the gland are quite pronounced.

Patient was a woman thirty-three years of age; she was in good health, had the usual children's diseases in childhood, and a curettage six years before. No pain or discomfort of any kind. She was at times a bit nervous, and occasionally had a sore throat. Her pulse rate was 90, but her heart was quite regular and in no way annoyed her, and she had none of the characteristic manifestations of hyperthyroidism and was a few pounds above her normal weight. Her thyroid gland was much enlarged, her neck measuring 15½ inches in circumference. All portions of the gland were involved and it would be described as a colloid goiter. She had had the enlargement since childhood, but during the last two years it had increased noticeably in size. Her chief interest in the matter was to be free of the cosmetic disfigurement which it caused. Such glands are nevertheless a menace to the health of the patient and ought not to be slighted.

Treatment. During the first two months the only medication received was 2 grains of potassium iodide after meals. She was placed upon the meat and stimulant free diet. Her neck at the end of this time measured 14¼ inches in circumference. She had continued in good health, but had felt the stimulating effects of the iodine. She had a mild degree of tremor, her heart was more sensitive, and skin reacted to slight irritation. The thyroid function was plainly increased during this period. There was no loss in weight, but she was more than usually sensitive to the hot weather.

During the next three months the iodide was continued in the same dosage and she was given a capsule at night of

Rhei pulvis.....gr. ii
Cascara sagrada.....gr. ii
Fel bovis.....gr. i

Beginning with the third month, she was given a series of six x-ray treatments, one treatment each week. The writer has observed that the x-ray is better borne and has a better effect on the patient if potassium

iodide has been administered previously in the manner described. At the beginning of the sixth month her neck measured 13½ inches in circumference. She was in excellent health and had no indication of hyperthyroidism. The iodine and laxative capsules were continued three months longer, when five more x-ray treatments at weekly intervals were given.

Twelve months after treatment began she had a thyroid gland not noticeable to casual inspection; her neck was 13 inches in circumference and she was in excellent health. It was still possible to palpate the enlargement in both lobes, however, and the iodide, laxative capsules, and diet were continued for four months longer. The medication continued for sixteen months.

Four months later she was carefully examined and had a neck 12¾ inches in circumference, the gland could not be seen, and only on deep palpation could a slightly enlarged left lobe be found. She was in excellent health, with no evidence of abnormal thyroid function.

Iodine, x-ray, diet, and clean bowels will relieve a large percentage of such cases, but no attempt should be made to do it in a few weeks. A gradual change is much safer for the patient. The iodine should be continued in such cases in spite of mild hyperthyroid manifestations.

Simple colloid goiter, of which this case is a type, is not necessarily a surgical condition. No type of thyroid enlargement is normal and it should not be slightly treated. Cases of the sort mentioned very frequently show at a later stage the characteristic manifestations of severe thyroid disease.

CASE X.—Patient was a small woman, aged 39, native of Austria. She first noticed enlargement in her neck in 1901, and although she suffered severely from headaches and tired very easily, especially in the summer months, she did not seek medical advice with respect to it until 1913, when she was given a simple tonic and vegetable cathartic. With the onset of hot weather in 1914, she noted that her neck was more troublesome, and in June she first came under observation. She was a small thin woman, nervous, skin flushed easily, no exophthalmos, heart sensitive, pulse rate 110, heart not dilated, constipated, with heavily coated tongue and foul breath. Throat dry and red, with hacking cough. She had a fine tremor and was muscularly very weak. The thyroid gland was about 2½ times normal size, very hard, and its surface had a shotty nodular feel. The gland was tender to palpation and caused the patient some pain. The stony hardness of the gland attracted attention, especially in the presence of mild atypical symptoms of hyperthyroidism. She was kept under careful observation for three weeks, during which time she received injections of antithyroid serum, and was given the meat- and stimulant-free diet, together with the rhubarb, soda, and cascara mixture previously mentioned. During this month the patient's general condition improved, but the gland increased a little in size and caused her more pain. Furthermore, a supraclavicular lymph node at the inner border of the sternocleidomastoid muscle was found during the last week and this gland increased in size and tenderness during the succeeding ten days. A clinical diagnosis of thyroid carcinoma was made and the patient recommended for immediate operation, to which she agreed. The right lobe, isthmus, involved lymph node, and the major portion of the small uninvolved left lobe were removed. Microscopic examination showed typical carcinoma of the right lobe, and enlarged lymph node. The left lobe was not involved.

Following the operation, patient was given several heavy doses of x-ray from the Coolidge tube, and after two months' interval a second series of x-ray treatments were given. She had the operation in August, 1914, and had been given 18 x-ray treatments by December 20 of that year. Patient made a good recovery from the operation. She gained 33 pounds in weight and except for an occasional headache continued well and was not seen again until November, 1915, a year

and three months after operation. At this time she had a typical condition of mild myxedema, and was given thyroid extract in small doses, which relieved her. The area of operation was in excellent condition and no recurrence or extension of the growth could be found. In March, 1916, the patient stated that during the last three weeks she had had pain in the right side of neck and right shoulder and had occasional attacks of palpitation. In other respects she was well. The deep tissues of the right supraclavicular space were found to be tender to pressure, and the right end of the scar was somewhat adherent to the underlying structures.

At this time the patient was given a further series of eight x-ray treatments over the operated area. She began also a series of injections of plant protein, which the writer has described elsewhere in detail. Her pain was relieved; there was no evidence of progressive involvement at the operation site. It was necessary to continue the administration of small doses of thyroid extract to control the myxedema. She was away from the city during July and August, but reported in early September, 1916, in excellent condition. The protein injections were continued during September. About December 1 the patient developed a bronchial cough and examination of her chest gave evidence of beginning involvement in the lungs. She was not seen again until March, 1917, when she was found to have lost weight, became dyspneic on slight exertion, and had a constant troublesome cough. X-ray examination of the chest revealed numerous metastases scattered through both lungs. There was no evident involvement at this time of the operated area in the neck. The patient grew worse rapidly and died from the pulmonary involvement in April, 1917, nearly three years after the original operation.

Cancer of the thyroid is nearly always superimposed upon a goiter of some years' standing. In other cases that have come under the writer's observation, thyroid enlargement without marked symptoms had been noted for several years before the change to a malignant condition was observed. In most cases thyroid carcinoma grows rapidly when once initiated, so that a period of nearly three years between operation and fatal outcome is quite unusual. The writer has had two other cases with similar treatment and similar result. He has likewise had four cases with early operation for cancer of the thyroid but no after-treatment, and death followed in all of them in less than one year and in each case there were extensive recurrence and infiltration at the site of operation.

Ehrhardt collected 200 reports of true thyroid carcinoma and in 104 the existence of previous goiter was expressly stated, and in only 21 cases was it expressly denied.

Thyroid hyperplasia, giving rise to the symptoms recognized as Graves' disease or exophthalmic goiter, has not, in the writer's observation, given rise to a later malignant growth. While the carcinomatous thyroid undoubtedly has some true thyroid function, as evidenced by the myxedematous symptoms following its removal and by the occasional observation of relief from such a condition when metastases have developed, it does not appear that the excessive activity found in Graves' disease has ever been noted in such glands. Any successful treatment of thyroid carcinoma must be prophylactic rather than curative.

These cases show a variety of types of thyroid disease and illustrate certain methods of treatment that experience has proven to have value. Each case is a problem by itself and requires a careful analysis of all the factors involved to get

the best results. Medical treatment is not a spectacular method, and the long-continued action of mild corrective measures is advisable. The gland is responsive to a variety of disturbing conditions and no method of treatment, medical or surgical, that confines its action to a direct assault on the gland, and does not remove the factors which disturb its normal functioning, can succeed in practice.

417 PARK AVENUE.

ORTHOPEDIC PRINCIPLES IN GENERAL MEDICINE.

By J. MADISON TAYLOR, M.D.

PHILADELPHIA, PA.

PROFESSOR OF APPLIED THERAPEUTICS, TEMPLE UNIVERSITY, MEDICAL DEPARTMENT.

THE general practitioner should be the first to observe the genesis of structural abnormalities which, unless promptly corrected, might become deformities or disablements. He should become expert at corrective manipulations, adjustments; appreciative of slight morphological anomalies; also expert in the use of simple apparatus and supports, and apply them early to incipient or minor orthopedic problems.

These constitute useful agencies for prevention as well as correction. Much should be done that is not yet done by guiding growth-forces when they begin to go wrong; in preparing structures to get the best from later treatments. These also form reliable remedial agencies in controlling disorders of the static and motor constituents of the body; in conserving mechanically impaired function; in correcting actual deformity while incipient.

Skillful manipulations, adjustments, replacements, are of paramount importance in preventing the development of structural alterations which may induce derangements of growth-impulse, or reflex perversions of, or loss of, function, shown by pain, tonic, spasm, rigidity, etc., due to impairment of cooperative action of collateral parts affording support, or of permanent disability of structures. When supplemented by judicious use of simple apparatus, supports, or traction agencies, by them often can be forestalled permanent damage.

Hence the logical divisions of orthopedics: (1) prophylaxis; (2) preparatory action, breaking ground for other agencies; (3) as the chief agency, and (4) as a form of after-treatment following upon acute disease.

Mechanical remedies are often capable of relieving pain and tonic spasm as well as, or better than, an analgesic. Especially valuable here are pressures on nerve-points, manipulation of indurated masses, passive and active stretchings, torsions, and passive hyperemia. A paramount law in pathology, capable of wide application in diagnosis and treatment, is that any disorder affecting one part of the body exerts a sympathetic effect, more or less marked, on any or all other parts. Here we have the domain of transferred pains, tonic spasm, compensatory action and over-action, inducing fatigue, strains, tension pains, and disability.

In many conditions where disability has existed for some time, the motor centers require re-training, *e.g.* after immobilization, paralysis, chorea, re-

flex irritations, tabes, also a large variety of limitations of motion in the vertebral column.

When active motion is limited or lost, as in paralysis, passive movements are needed to aid nutrition and to reinforce centers long dormant; then to lead to and enforce renewal of active movements, resistance; to wake up dormant motor cells and respiratory rhythms; *e.g.* by use of constrictive hyperemia, by systematic movements, free or against resistance, or by the guiding hand.

Intelligence is needed to select the right movements or restraints; so also is plenty of time and opportunity for training and supervision.

1. *Orthopedic Prophylaxis, e.g.* in Poliomyelitis.—Here many neurons in the anterior horns are deeply hurt; some will recover fully, some partially, others not at all. After the acute stage the patient should be kept at absolute rest for many months till the inflammatory effects are well past.

Later passive movements must be made, and full active movements encouraged or enforced, by both patient and family. Every assistance must be afforded to depressed centers, beginning with rest, later using support, full or partial, till spontaneous action can be elicited and maintained to regain muscle-tone and central repair, and to prevent deformity, contracture, and atrophy. Contracture and deformity may, and often do, occur during the initial stages.

Next, the paravertebral vasomotor subcenters need manipulation to encourage local repair through increased blood impetus.

Contracture of one muscle leads to a stretching, and in the case of a paralyzed or weakened muscle to a more or less permanent lengthening, of the opposing muscle; even should there be complete recovery, the overstretched muscle will, nevertheless, lose integrity and efficiency. Hence orthopedic measures are needed in early as well as late stages of infantile paralysis. The stronger muscles must not be allowed to contract, nor to become immobilized, fixed.

Normal autogenesis must be encouraged; similarly of *cerebral paralysis and hemiplegia*. Immobilized muscles will atrophy, but this is temporary, not permanent; they will recover through restored function, rehabilitation, training.

Fixation too long applied tends to weaken extremities, hence these must be exercised by Faradism, also by educating the psychomotor function, volition, patiently, precisely, and persistently. The Zander apparatus is valuable in subacute or chronic states to prepare the parts for later movements, active and passive, by shakings, torsions, forcing pliancy and mobility in stiff joints and rigid ligaments and tendons. Recovery depends on restoration of nutrition in the cells in the spinal cord, first by adequate rest and next by gentle activation, later by compulsory and complete actions, in full accord with functional endowments.

In many septic and other acute joint-affections early passive active and resistant movements are imperative, used in connection with vaccines, bacterins, or soon after joint-opening; also heat, passive hyperemia, supporting bands, splints, casts, or traction methods (Bier, Gurdon Buck, Croly, and Bardenhauer) in fractures, dislocations, etc. In fractures of the wrist it is recommended to begin

on the fourth day; of the elbow, on the tenth or twelfth; impacted fracture of the humerus, on the second or third day; unimpacted fracture of the humerus, second or third week. Leg braces are for the purpose of facilitating walking only; also normal use of the legs and restoration of motor centers.

In *scoliosis* passive and active movements do not cure, but will aid in keeping the backbone fairly straight, and in making it somewhat straighter. Areas in vertebrae found rigid, or morbidly impaired, can be relieved by gentle, forceful hand-pressures, thrusts, repeated until mobility is restored. In a seance begin by encouraging active resistances, follow by passive compulsions, never neglecting mobilization of the spinal column, especially where it is rigid or out of alignment, which is most conspicuous in the group of vertebræ affected.

2. *Orthopedic Preparatory Treatment*.—In septic joints, and equally after trauma; often heat, immobilization, sunlight, heliotherapy, gentle passive movements, are necessary to loosen, to stretch, and reduce adhesions; then gradually secure freer mobility, and then proceed to compel active movements. One step prepares the way for the next. Often after the whole of the tissues are involved, the capsule thickened, cartilage destroyed, adhesions in the joints and tendon-sheaths formed, gentle but forceful manipulations should be used, which must not tear the reparative effects of the plastic lymph. Work slowly but persistently. *Do no harm*.

3. *Orthopedia as Chief Remedial Measure*.—In practice, often prophylactic, preparative, continuous, and persistent mechanical measures are best grouped together and employed.

At each stage decisions and acts must be clear and precise. Lateral curvature and immobilization of the thorax needs all these measures. It is a common mistake to get the idea that simple exercises will cure curvature; always special forms and directions of force are needed, often with powerful over-corrections and temporary fixations, such as spinal braces. Simple, rightly chosen means, consistently pursued, are best. The only test of program is by exact measurements and fluoroscopic watching.

The causes of scoliosis are partly lack of right action and right position, but deeper causes must be searched for. They are often found in nutritional enfeeblement in infancy; in early disease; in early tuberculosis; in tonic spasm, local or general; in central disorder or to morbid psychism; in strain, as of the sacroiliac joint.

Judicious muscle training is the key to sacroiliac treatment; first to overcome spasm; next to train the wrongly acting muscles. Antagonistic muscles must be stretched, often forcefully; also nearby tissues, adhesions, and ligaments; by hand best, also later by apparatus and by active movements. The Zander apparatus is again useful as preparation, or as a continued auxiliary measure.

Rigidities or Contractures After Injuries.—Use first manipulations or heat, or both; then passive movements; later, active and opposed movements. The guide is the degree of inflammation present, rather than the amount of pain.

Limitation of movement is commonly due to fixation of musculo-tendinous insertions, of fibrous tissues, of aponeuroses, of tendon sheaths. These should be plucked apart, lifted, separated. First of the overlying dermal and subdermal structures, reaching down to the lowest movable masses.

Progress is difficult to maintain. In atrophic joints, arthritic deformities, after removal of septic foci tonics and eliminants are also required; passive hyperemia, heat, electricity. Sometimes the chief difficulty is nutritional faults. Here voluntary movements of the truncal structures are of first importance, to be followed by passive mobilization, thrusts, torsions, etc.

In long damaged joints changes occur in epiphysis or diaphysis, hence the morphology is changed; the primary lesion often cannot be found if obstructive masses prevent. Then bone operation is indicated; a piece should be taken out.

In *hypertrophic arthritis* avoid all stimulation and go slow on action. Good hygiene is needed, careful diet, colon irrigations for not only bowel cleansing, but also for skin and kidneys; suitable hot or cold baths. Counter irritations are occasionally most helpful.

4. *Orthopedic After-Treatment*.—For all traumatic joint effects, for sprains, dislocations, fractures, acute joint- troubles, septic, hypertrophic or atrophic; for clubfoot and for wryneck (which is apt to recur) tenotomy may be needed; heat, braces, exercises to alter nutrition and stagnation in the soft structures; also of the bones of the head and neck, which are often deformed.

Spasmodic torticollis always has a psychic element. Treatment is explanation, suggestion, exercises, etc. Tenotomy is often needed here; also mobilizing of structures at the base of the skull; e.g. chiropractic thrusts. This thrust is efficient by forcefully overcoming the over-tense muscle, which acts compensatorily, protecting the original injury.

In flat-foot temporary supporting of the arch is useful; better Longstreth's "elevation." The real treatment is to walk barefooted, to exercise the small muscles between the bones, also ligaments and fascia; to walk pigeon toed; to sit upon the heels, toes straight out behind, on side of the bed. (See article by author, *New York Medical Journal*, Nov. 10, 1917.)

For tuberculous joints: fixation, dry heat, heliotherapy, quartz lamp, Hereaus, Kromeyer, Alpine sun-lamps, violet rays.

Braces or splints should never be used as curative agencies, but for two purposes: to retain a bone or joint in its proper mechanical relationships without strain, while nature, or special treatment, is doing its best to restore or to improve the mechanical efficiency of some part of the skeleton impaired by disease or accident, to facilitate normal action, as in walking.

Get the right concept of the purpose of the leg-brace. This is to enable the individual to enjoy the privilege of being to that extent nearly normal; it promotes general well-being by encouraging the sufferer to enter into so much of active life as he is able. It enables the stronger muscles to remain normal and not become hypertrophied; to act in conjunction with the weaker complement in poise. It at least does no harm. It does not cure the

source of disease. Without it, oftentimes, the child could never have been able to walk; with it, walking is much more easy, agreeable, efficient and more normal.

Uses of Adhesive Plaster.—It is an art—which also demands scientific precaution—to use adhesive plaster safely, especially when fixation is needed for as long as possible. Thorough asepticizing of the surface is necessary; hairs should be shaved and surface cleaned with benzine, turpentine, alcohol, or, as Torrance Rugh recommends, by washing with saturated solution of borax.

Skillern (*Pa. Med. Journ.*, September, 1911) uses also iodide of mercury or formaldehyde in solution to sterilize hair follicles and sebaceous glands. Much art is shown in making choice of width of strips, in reinforcing, in distribution with regard to bony and other prominences.

Postural Deformities.—Many deformities arise during the plastic years of childhood and youth due to one or more of several causes, developmental defects, faulty nutrition, metabolic disorders, demineralization, weak hearts often displaced; to ductless gland defects, along with minor mental peculiarities or defects plus faulty habits, lack of incentive to, or of opportunities for, normal activities. Also there are contributory factors more or less efficient, such as defects of sense organs, of sight, of hearing, of pressure from adenoids, pharyngeal diseases and dentural errors. These affect habits of standing or sitting or moving which aggravate and emphasize postural limitations. The products are deformities which are labeled postural. Oftentimes early rickets, not grossly marked, is the starting point.

Postural deformities occur more frequently among poor and ill cared for children, but also among the more favored classes. They may readily become serious, exerting harmful effects on organic competence, constitutional vigor, and upon mental alertness and efficiency. Among these are round and forward shoulders, curved backs, round and hollow; weak feet and ankles. Indeed weak feet are frequently at the root of errors of posture, limiting, as they do, free activities and ease of standing or walking. They also cause strange transferred pains. Minor forms of scoliosis are frequently observed.

In standing one side is "favored," hence displacements occur to one or other side, the displacements being in by far the largest number of cases to the left; the curve of the spine to the left, and the left shoulder higher than the right, the right side of the thorax is carried back, inducing a physiological rotation of the vertebræ toward the concavity of the curve, which carries the ribs back on the right side and so displaces that side of the thorax and shoulder girdle backward on the right. On lying down the curve disappears, showing it is not a structural curve.

Physiological curves are always single or local curves in contrast with the more frequent double curve of structural defects. Single structural curves do occur, the rotation being then on the convex and not the concave side. These posture curves require only nutritional and developmental measures with possibly an elevation to the shoe. The more pronounced instances of physiological curves may readily become structural.

Orthopedic surgeons exhibit discouragement in the treatment of such cases probably because they fail to secure needed domestic cooperation. The chief remedial agency is to attain full control of the child; to achieve its personal cooperation, to arouse wholesome pride and ambition. When this is secured, along with essential nutrition and other environmental betterments, good results can be counted upon.

Full correction of all determinable errors in sense organs is imperative. Opothrapy is the most efficient form of medication, though the old-fashioned and now neglected cod liver oil and phosphorus tonics are not to be omitted. Sea air, open air, full feeding, long periods of partial rest, and arousing of the play impulse, will carry one far toward restoration.

1504 PINE STREET.

THE PROBLEM OF VENEREAL DISEASE IN ITS RELATION TO PENAL INSTITUTIONS.*

By EDITH R. SPAULDING, M.D.,

BEDFORD HILLS, N. Y.

DIRECTOR OF THE PSYCHOPATHIC HOSPITAL OF THE LABORATORY OF SOCIAL HYGIENE,

WHILE controversies are being carried on as to whether the honor system or self-government is more efficacious in remodeling the criminalistic man and helping him to readjust himself to social conditions, and whether a course in domestic science or an industrial training is better adapted to fit a woman to be self-dependent, the problem of venereal disease which needs no prolonged argument, is being neglected. As clear cut and as important as the problem is in the community in general, it becomes much more definite when related to the population of our prisons and jails. If society does not assume the responsibility for these individuals, and treat them adequately, it must face the fact that, later on, they will not only be a source of danger in the community, by causing the spread of the disease among innocent persons, but that a certain percentage will become so incapacitated by the disease, either mentally or physically, that they will be public charges.

Of the two venereal diseases which are the most prevalent—gonorrhea and syphilis—the latter is perhaps more far-reaching in its social aspects because it affects the succeeding as well as the present generation, and therefore seems to demand the first consideration. The following figures will show the prevalence of syphilis in some of our reformatories and penal institutions where laboratory tests have been adopted as a routine procedure in the physical examination.

Among 500 cases¹ studied at the Reformatory for Women at Framingham, Mass., 44 per cent. had positive Wassermann reactions, while 10 per cent. were doubtful. In 440 cases² studied at the New York State Reformatory for Women, at Bedford Hills, 48 per cent. gave positive results, while in Auburn prison, New York,³ the percentage among the women was 33 and among the men 16.

*Read at Willimantic, Conn., October 18, 1917, before a joint meeting of the Windham County Medical Society and the Connecticut State Medical Society, together with the Connecticut Society of Social Hygiene and the Connecticut Society for Mental Hygiene.

Dr. Davis* reports that in the Department of Correction in New York, all women admitted are given the Wassermann test. I am also indebted to her for the information that during the last year 55.83 per cent. of the women committed under the indefinite sentence were syphilitic.

Dr. Glueck* states that among 940 cases admitted to Sing Sing prison between August 1, 1916, and May 1, 1917, 18.9 per cent. gave a one, two, three, or four plus Wassermann reaction, while but 10.3 per cent. gave a four plus Wassermann reaction.

The high correlation in the percentages of syphilis in the various institutions for women quoted above is due doubtless to the large number of prostitutes included in their populations. A special study⁴ made of 243 prostitutes at Framingham showed 65 per cent. giving a positive Wassermann reaction and nearly 10 per cent. more giving a doubtful Wassermann reaction. It is interesting to compare this with an examination reported by the Baltimore Vice Commission,⁵ which shows 63.7 per cent. of 289 prostitutes to have syphilis.

From the earliest times prostitution has existed in spite of all conceivable attempts at repressing it, but it is only in recent years, with the increased knowledge of laboratory tests for the detection of venereal diseases and the increased knowledge of the diseases themselves, that true realization has come of the mental and physical devastation which has resulted from it. According to Aschaffenburg⁶ "prostitution was originally instituted by priests for the honor of the divinity and the benefit of the temple, and later put into practical form by statesmen like Solon. . . . Louis XI of France tried to abolish it altogether and founded places of refuge for fallen women. On his return from Palestine he ordered it to be completely exterminated. The concealed prostitution that immediately began to flourish everywhere, however, compelled him before a year had elapsed to repeal the order and assign certain streets to the use of prostitutes." And so it has continued till the present day, when in the year 1917, a city in our own country after repeated attempts by the citizens to effect such a procedure had failed was finally ordered by the Federal government to close its segregated district because of troops quartered in the vicinity. As a result 4,000 women who had been plying what up to that time had been considered in the city a legitimate trade were without employment and were liable to arrest if they returned to their previous occupation. Whatever the solution of the moral problem may be which has remained unsolved through so many centuries, of one thing we are certain, and that is that the spread of physical disease should be as far as possible controlled, not, however, by the physical examination of prostitutes,† which in all instances has proved ineffectual, if not a farce, but by recognizing venereal disease as contagious and infectious, and treating it accordingly.

The increased knowledge of syphilis which has come to us since Schaudinn and Hoffmann discovered the *Spirochæta pallida* in 1905, and Wasser-

*Personal communication.

†Bulkley⁷ some years ago emphasized the need of controlling the spread of venereal disease in prostitution by examining the man rather than by the old and unsatisfactory method of examining the woman.

mann, Neisser, and Bruch established the serum diagnosis of syphilis in 1906, and Plaut the Wassermann reaction of the cerebrospinal fluid in 1908, is remarkable, but would be disheartening, interesting as it is, had it not been offset by Ehrlich's discovery of salvarsan in 1909. Even before the introduction of the Wassermann test there were appalling statistics published of the prevalence of syphilis in the various countries. These ranged between estimates of from 3 to 5 per cent. in the general population of Prussia and Sweden to 45 per cent. and even 77 per cent. in groups of selected persons, such as clerks and merchants, between the ages of 18 and 28 years in certain of the German cities.³

The effect which syphilis has on the birth rate and the large numbers of women and children who are infected innocently will show to some extent the possibilities of further harm which untreated syphilitic delinquents may have in the community. Fournier⁹ describes 44 pregnancies among women recently infected with syphilis. From these there resulted 43 deaths and one living child. Four hundred and ninety-one pregnancies in syphilitic families, in which one or both parents were syphilitic, resulted in 382 deaths, or 77 per cent. Taking into account the most favored cases in which the father only was syphilitic or had had previously prolonged treatment there were 68 per cent. of deaths. Gregg¹⁰ reports in the families of 70 syphilitic patients 133 deaths, 52 miscarriages, and 8 stillbirths. Fournier also emphasizes the large number of women who are infected innocently. About 5 per cent. of 887 cases seen over a period of 27 years had syphilis of non-venereal origin, while 19 per cent. were married women who had received the infection from their husbands. In our own country we have ample evidence of the number of innocent victims of the disease. During a period of 27 months 600 children under 12 years of age passed through the venereal ward of the Cook County Hospital in Chicago.¹¹ Of these 16 per cent. had syphilis and 84 per cent. gonorrhea; 60 per cent. of the children had been innocently infected; 20 per cent. showed congenital conditions, and 25 per cent. had been assaulted by diseased persons.

Bazeley¹² shows by studies made at the Boston Psychopathic Hospital that there is increasing authority for considering the infectious psychoses and psychoneuroses to be the last offshoots of luetic heredity. He has also shown in a study of children under 15, constituting social problems, that those children showing evidence of congenital syphilis showed a larger proportion of feeble-mindedness and retardation, were more delinquent, and had greater defects of vision, hearing, and speech than the non-syphilitic group.

Perhaps the greatest danger of syphilis as a cause of social inefficiency lies in the fact that it may do so much damage to the central nervous system. Williams¹³ states that 10 per cent. of the patients who enter the Massachusetts State Hospitals for the Insane are suffering from syphilitic mental disease. In New York State there are 12.7 per cent., while in Ohio there are 12 per cent. Over 16 per cent. of 3,213 cases at the Boston Psychopathic Hospital¹⁴ show a positive or doubtful Wassermann reaction in blood serum or spinal fluid. Williams,

in an interesting study, has made a compilation of the number of years lost in the lives of 100 cases coming to autopsy at the Boston State Hospital, whose death was caused by syphilitic mental disease. He estimated that by the premature deaths a period of 2,000 years was lost in the community. Their death represented a financial loss of over \$212,000, and their medical care had cost the State over \$39,000. One hundred and nine children had been left as public charges. These estimates did not include the other dependent members of the family or the physical and mental defect of other people resulting from the 100 infections. Williams estimates that there are at present at their work in Massachusetts 1,500 persons who in the next five years will be committed to state hospitals on account of syphilitic insanities. In the State of New York there are 3,000 such individuals.

Syphilis as a cause of feeble-mindedness, of organic disease, and of ill health in general is less easy to compute. It is, as we all know, a very great factor in the community. This point has been emphasized in an exceedingly forceful and stimulating address by Sir William Osler¹⁵ on the prevention of venereal diseases, delivered last spring.

Although gonorrhea does not cause diseases of the central nervous system, its effect on the birth-rate and on vision, its pelvic and abdominal complications, and its rôle in causing cardiac conditions and arthritis, together with the greater prevalence of the disease, make it almost as formidable a social factor as syphilis. The following figures will serve to demonstrate its prevalence among delinquent women. At the Reformatory for Women at Framingham, Mass., there were 75 per cent. of gonorrheal infections among the total population.¹⁶ This was based on bacteriological evidence as well as on clinical symptoms. At the New York State Reformatory at Bedford Hills, N. Y.,¹⁷ 73 per cent. showed the presence of gonorrhea, according to the complement fixation test alone. Among 243 cases of prostitutes studied at Framingham over 98 per cent. had gonorrhea. Ninety-two and one-tenth per cent. of the 266 prostitutes studied by the Baltimore Vice Commission¹⁸ also had gonorrhea. Among alcoholics at Framingham who had not been arrested for any offense against chastity 52 per cent. showed evidence of gonorrhea. In a miscellaneous group made up of women in whose history there was no known sex promiscuity, 44 per cent. had gonorrhea. This may not seem so high when we remember that Neisser believed that 45 per cent. of all women in the community were infected with gonorrhea.¹⁹ No satisfactory statistics on this disease appear to be forthcoming from men's prisons, but we remember that Neisser²⁰ estimated gonorrheal infections among the male population in general as 75 per cent., while other authorities estimate it as high as 80 and 90 per cent.

It may be of interest to keep in mind the results of gonorrhea in the community. Norris²¹ states that by sterilization and abortions gonorrhea does more to depopulate this country than any other one cause. Other authorities say that from 30 to 50 per cent. of all childless marriages are directly caused by gonorrhea. In the opinion of over 600 physicians 40 per cent. of all gonorrheics suffer from pelvic inflammatory conditions. Six different authors believe

that 25 per cent. of acute cases and 50 per cent. of chronic cases show pelvic complications. In the reformatory cases we found that 67 per cent. presented symptoms of pelvic inflammation, while 40 per cent. became surgical cases, either having had or needing abdominal operations. We also found that the number of children in the families of gonorrheics was over one and one-half less than among families of non-gonorrheics, and that there were 35 per cent. of one-child sterilities among these infected. While the limitation of the birth-rate may be considered desirable among the delinquents themselves, it certainly will not be considered so when it follows the ramifications of the same infections as they spread out in the community.

Most of our cases seemed to run an uninterrupted course sometimes for a period of 25 years without having treatment. During that time they were continually a source of infection. Only 15 per cent. of the cases had received treatment during the first year of the disease, and, as we all know, unless a case is treated at the beginning of the infection, treatment for many months if not years, is necessary to control even clinical symptoms. Only 1 per cent. of our patients had received adequate medical treatment, and 53 per cent. had had no treatment whatever.

We must not forget the social inefficiency caused by this disease through blindness, as it is estimated that from 30 to 50 per cent. of all blindness and 80 per cent. of blindness of the newborn results from gonorrhea.

Treatment.—Various institutions in this part of the country have been treating syphilis with up-to-date methods for some years. Dr. Fernald* at the Massachusetts Reformatory at Concord, Mass., has been giving salvarsan since 1910, when he received some of the second lot sent to this country. Dr. Fernald, who has kindly allowed me to use his unpublished figures, finds an incidence of less than 7 per cent. among the inmates of the reformatory. Of the cases under treatment he believes that 50 per cent. are cured before they leave the institution. Dr. Haecox* at Auburn Prison in New York introduced the Wassermann reaction as a routine procedure in all admissions on October 1, 1915. It has also been possible for him to administer a limited amount of neosalvarsan to all cases showing a four plus reaction. Furthermore a definite appeal was made in the annual report for an adequate supply.

In our small hospital at Bedford Hills repeated doses of diarsenol are being administered once a week in the treatment of syphilis, together with a weekly injection of salicylate of mercury. While some of our patients have received from fifteen to twenty treatments of diarsenol, every luetic woman in the reformatory is receiving at an out-patient clinic of the hospital five treatments of diarsenol in addition to her other anti-syphilitic treatment. Similar treatment is being given all the syphilitics at the Reformatory at Framingham, Mass., by Dr. Sullivan. It may be asked how the money for so expensive a treatment can be procured. From our brief experience with such bodies we believe that if one goes before the legislature and explains frankly the effect of untreated cases of syphilis

*Personal communication.

returning to the community, money will be forthcoming for any amount of salvarsan or its equivalent which is desired.

Regarding the effect which energetic treatment of syphilis may have on the conduct of the patients we have only to look to our psychopathic hospitals, where such treatment is being given, to see marked improvement in behavior in cases of syphilis of the central nervous system following treatment. While syphilis itself does not often appear to be the direct cause of delinquency, the treatment of syphilis in delinquents often improves their mental condition to a marked degree, and makes it possible for them to readjust themselves to their environment. Southard⁹ mentions such a case as this which, while exhibiting from childhood a psychopathic personality, also showed evidence of a diffuse cerebrospinal syphilis. While the psychopathic personality was not markedly benefited by antisyphilitic treatment, still the additional symptoms caused by the cerebrospinal syphilis were eradicated. The patient ceased to have convulsions and, although the mental tests showed that she ranked in the subnormal class, she was apparently better equipped to make the necessary social adjustments.

We know of a woman committed several times to different institutions for forgery. Since her release from the State Reformatory several years ago she has held responsible positions in various institutions. She had cerebral lues and suffered from headaches and insomnia, which disappeared after a few treatments of salvarsan. It is difficult to say to what extent syphilis was the cause of her antisocial acts, but treatment of the disease has undoubtedly been a help in enabling her to adapt herself to the laws of the community and hold positions of responsibility.

The treatment of gonorrhea, especially in large institutions for women, presents perhaps a more difficult problem. At the Reformatory for Women in Framingham, in which the population ranges between 300 and 400 women, gynecological treatments were given twice a week to all cases of gonorrhea. At least 250 treatments weekly or 1,000 treatments a month were given. One must realize also that in many cases an eight to ten months' treatment was necessary before clinical symptoms alone disappeared. For medication, tincture of iodine or a solution of silver nitrate 10-25 per cent. has been applied to the interior of the cervix and to the vaginal mucosa. Besides this, tampon treatment has been given with boroglycerin or ichthyol and glycerin and (before the war) a solution of picric acid.

One often wonders if the unsatisfactory results obtained warrant the amount of energy expended in the treatment. However, the extreme virulence of many of the cases leaves no alternative even though the best treatment is inadequate and cure impossible. Furthermore, the effort may be considered worth while if it succeeds in emphasizing in the patient's mind the seriousness of her condition and makes her realize the necessity of further treatment after she has returned to the community.

Veneral Disease and War.—At a time when venereal disease constitutes one of our greatest war problems we may be pardoned for referring in the discussion of our smaller problem to the much

larger one which is facing society to-day. One-third to one-fourth of the British army²⁰ is said to have contracted venereal disease since the beginning of the war, and it is also said that in France the prevalence of these "plagues" (gonorrhea and syphilis) is "horrible."²¹ Gaucher²² has said that whereas before the war, at the St. Louis Hospital, one patient in ten was a recent case of syphilis, in the first months of the war, this proportion increased to one in six, while in the next eight months it was one in four.

It is interesting to look back at the history of syphilis and compare its first appearance in Europe with its prevalence at the present time, noting the close relation which has existed from the earliest times between war and the spread of the disease. It will be remembered that syphilis is supposed by some authorities to have made its appearance in Europe after Columbus returned to Spain from his discovery of the West Indies in 1492.²³ At that time Charles VIII of Spain had gathered together great mercenary armies for an invasion of Italy. Soon the disease spread not only through Italy, but also to all parts of Europe to which the soldiers traveled. Although this was over 400 years ago and although much has been learned of the disease since, especially in the last 10 years, it is even now one of the greatest problems of the present war. Gonorrhea has remained quite as much a problem through many centuries. We hear of it first from the oldest Egyptian medical records, about 1550 B.C.; in Japanese manuscripts as early as 900 B.C., and in the Old Testament in Leviticus.²⁴ It has apparently thrived from that time until the present day in spite of Neisser's discovery of the gonococcus in 1879 and later discoveries in treatment and in prophylaxis, so that at the present time it is the most prevalent of the infectious diseases with the exception perhaps of measles. To quote from a recent article by Lyster: "The gonococci have probably quite as ancient and respectable a lineage in biology as the pneumococci. The same relentless scientific measures that are used in the one case must be applied in the other, and no fake sentiment must be allowed to interfere in the efficiency of their application." However, a social conscience is being aroused and there is no better evidence of it than that the most conservative of the New York papers has printed a series of articles, which describe our failure to control the situation on the Mexican border and recount the dangers and prevalence of syphilis and gonorrhea in general.

The attitude of our War Department toward venereal disease and the emphasis laid on it is encouraging. Every effort is being made to meet the situation, with the following four methods of attack:²⁵ (a) Social measures to diminish sexual temptation. (b) Education of soldiers and civilians in regard to venereal diseases. (c) Prophylactic measures against venereal diseases. (d) Medical care.

The amount of interest shown in the subject by the general public through a variety of organizations, both medical and non-medical, is most interesting. Alcohol is being kept from the neighborhood of the camps. The attempt is made to eliminate prostitution from their vicinity. Recreation centers are being established where men may meet

their women friends and may come in touch with women of a good type. Organized sports are being made compulsory. The work of the Y. M. C. A. and also the Y. W. C. A. is of inestimable value. The whole movement is recognized frankly to be one to combat venereal disease, which in some companies of the European armies on their way to the front is said to have incapacitated more men than have been incapacitated in other companies while under shell fire. Whether or not the commanding officers will consider prostitution necessary for their men and will see to it that the vicinity of the camp is free from undesirable resorts and saloons will be largely the result of this openly expressed public opinion. Exner²⁷ reports that on the Mexican border there were but two such protected camps. He says of one: "No more contented, more orderly, better disciplined, better trained, more efficient, or more loyal body of troops could be found anywhere on the border. These facts can be readily verified from anyone conversant with the situation. Furthermore, these men were proud of the moral reputation of their regiment. Many of the men said to me, with a ring of pride, 'Oh, we have a clean bunch here.'"

The annual report of the Surgeon-General to the Secretary of War shows the incidence of venereal disease in our army during the last three decades. In the first period from 1886-1898 the incidence of venereal disease was 7.8 per cent. During the period beginning with the Spanish War in 1898 and lasting until 1909, the rate increased to a ratio which ranged between 13.5 and 17.4 per cent. With the introduction of prophylaxis and systematic measures of dealing with the situation, and with the use of the Wassermann reaction the ratio during the third period, from 1910 to 1915, again decreased to a rate which ranged from 6.5 to 10.5 per cent. Exner²⁸ shows that on the Mexican border the extent of prostitution was in direct ratio to its accessibility and that the venereal rate under prophylactic treatment, as compared with indulgence in prostitution, was surprisingly low. It is interesting to consider the attitude of the English in refusing to make use of artificial prophylaxis²⁹ even at the present time, in the fourth year of the war, after the efficiency of their army has suffered so much through venereal disease. Preventing venereal disease by prophylactic treatment may be considered in the same category as the prevention of mental disease when the earliest symptoms present themselves. Failure to do either of these things seems to us not only short-sighted, but also unethical.

Recommendations for the Control of Venereal Disease Among the Criminalistic Population.—1. We believe that wherever a physical examination is necessary in the case of individuals passing through our courts it should include laboratory tests for gonorrhea and for syphilis. A physical examination is necessary in every case which is under the care of the State for any period of time, whether it is in a penal institution, an industrial school, or a jail. All cases found to be positive should receive treatment.

There is in Massachusetts a law³⁰ which we understand also exists in Connecticut, which states that inmates of public, charitable, or penal insti-

tutions shall be held for treatment of syphilis while the disease is in a communicable form. This law is of great benefit in bringing extra pressure to bear in forcing any uncooperative individuals to receive treatment.

2. Provision should be made in the community for hospital treatment of venereal disease to encourage care of such infections in their earliest stages and for follow-up work of those cases whose treatment has been begun in institutions.

3. We should not forget that the question of mental defect in the community is closely associated with that of venereal disease, as well as with delinquency. When we realize the real need of segregating the feeble-minded and are able to care permanently for this class of social inefficients, we shall remove a great source of infectious disease from the community. Twenty-three per cent. of the women at the Reformatory at Framingham, who were fit subjects for permanent segregation on account of their mental defect, showed 90 per cent. of gonorrhea and over 60 per cent. of syphilis.

4. It is believed by authorities both in Europe¹ and in America² that before the war is over the need will be recognized for a law requiring the notification of these diseases which will place them on an equal footing with other contagious diseases, will make treatment compulsory, and will tend to lessen the danger of further infection.

5. At some future date when our probation and parole departments have adequate medical equipment, and there is more emphasis laid on therapeutics in the treatment of delinquency, examination may be made also of the families of delinquents. At the Boston Psychopathic Hospital³ an effort is made to bring to the hospital for examination the wife or husband of every syphilitic patient treated and the members of the patient's family under 18 years of age.

Stokes⁴ in a book on syphilis, which is entitled "The Third Great Plague," says: "There are no signs more hopeful of the highest destiny for humanity than that of to-day which marks the transition of disease from a personal to a social problem." When the public is told through the daily paper that gonorrhea and syphilis are the most prevalent of all diseases with the exception of measles and that while over 19,000 cases of tuberculosis were treated in the city of New York in 1916, there were over 20,000 cases of syphilis treated, it is going to be more alive to its responsibilities in the whole situation.

Paton⁵ has recently said: "The present catastrophe which threatens civilization is one of the tragic results of attempting to organize society in order to satisfy theoretical conceptions without taking cognizance of the fundamental laws which govern human nature." Again, "The priest has told us what men ought to become, the poet has recorded all his dreams of an idealized race, while the historian has given us interesting pictures of what human beings were supposed to have been; but man, as he actually is, has only recently become the subject for study." The activities of many societies and their frank attitude toward the situation are evidence of a genuine desire on the part of the public to face things as they are and to assume responsibility for them.

We must meet a situation in the European War which will call forth every bit of strength and economic efficiency possible. If by adequate treatment of our dependent population now in penal institutions we can increase their economic, as well as their social and moral efficiency, let us by all means do it. It will be one of the bits for the men and women who stay at home to push with all the resources at their disposal. The great awakening toward the problem in the war should be a tremendous aid in getting support in this more limited campaign, and should help materially to shake off the inhibiting shackles which have held us in the past and prevented us from adequately meeting a very concrete situation. There is no class of people who can do more toward accomplishing this than the physicians. They have always appreciated the need, but on account of the ignorance of the public on the subject have feared to violate the ethics of the profession and take a definite stand which would doubtless cause undesirable publicity. This obstacle is being rapidly removed. The public is craving education and there is little doubt that means will be forthcoming now for all the help needed in the treatment of venereal disease, at least where it is under control in penal institutions.

MACROSCOPIC AND MICROSCOPIC FINDINGS IN POLIOMYELITIS.

By JOHN H. LARKIN, M.D.,

NEW YORK.

PATHOLOGIST TO THE STRECKER MEMORIAL LABORATORY, CITY HOSPITAL, BLACKWELL'S ISLAND.

MACROSCOPIC examination of the cases studied at autopsy included examination of the brain, cord, and membranes. Microscopic examination included the cord, ganglion cells, interstitial changes in the anterior horns, pons, peripheral nerves, and the internal viscera. For such study all tissues were hardened in formalin; embedded in paraffin and stained by several methods, namely, hematoxylin, eosin, Giemsa, Van Gieson, Nissl, and other selective stains; special stains for fat, including Marchi, Sudan III, and Scharlach R. Frozen sections were made of tissue from all cases.

The gross appearance of the brains in the cases examined was not at all characteristic of the lesion. It can be said, however, that in one case of the fifteen the brain tissue seemed to distend the dura mater, so much so as to produce a distinct softening of the convolutions, and upon more minute examination the color of the pia was found to be of a distinct copper-blue color.* The brain tissue was soft and somewhat edematous in this case. There were no distinctive gross lesions to be made out in the brain tissue of the other cases, except that in some there appeared to be a distinct edema, which was more prominent in the sulci. Examination of the brain at various levels, outside of the edematous condition referred to, which involved both the gray and white matter of the brain, gave negative results.

Macroscopic examination of the cord revealed very varying pictures as regards the levels most involved. In the more typical cases, in the upper cervical region, in the position of the anterior horns, a distinct reddish-pink color stood out in sharp contrast to the white matter of the cord, somewhat simulating the letter H. In this region the tissues seemed to be depressed below the level of the white matter; the horn seemed to be distended. There were no evidences of distinct hem-

*The case of Annie Martincowitz, noted in Dr. Walter Lester Carr's paper, is illustrative of the stuporous or comatose type.

orrhages at these levels. Sections below the upper cervical and the various dorsal and lumbar segments showed no gross anatomical change. Distinct softening in some areas was made out. These were sometimes unilateral and sometimes bilateral.

Gross Examination of Membranes.—No distinctive changes could be observed in the dura mater. Upon removing the dura and minutely inspecting the pia there was seen, in the majority of the cases, an edema without any noteworthy changes. This edema seemed to infiltrate into the sulci. In one case (Dr. Carr's, which is described above), the pia mater showed enormous capillary distention, but without the appearance of free blood in the interstices of the pial membrane. This engorgement seemed to be entirely venous. There was no evidence of acute leptomenigitis observed in the cases examined.

Examination of the spinal meninges showed no gross macroscopical alteration. In some cases there was a slight accumulation of serum with moderate distention of the blood vessels in the meninges, but this was not a constant condition.

Macroscopic Examination of Viscera.—The majority of the cases showed more or less macroscopic evidence of bronchopneumonia. Macroscopic examination of the hearts in all cases proved negative. No gross alterations were found in the stomach, pancreas, kidneys, or adrenals.

In all cases examined there was a regular lymphatic hyperplasia of the mesenteric lymph nodes, the measurements of some reaching from one to one and one-half cm. in diameter, and on cross section were deep red in color; some were hemorrhagic and edematous. This was a general and constant finding in all cases.

Upon inspection of the gastrointestinal canal there was regularly found a hyperplasia of the solitary lymph nodules, and Peyer's patches in the region of the ileocecal valve showed intense hyperplasia, but in none of the cases had actual ulceration occurred.

Macroscopic examination of the spleens showed enlargement, and upon transection revealed a distinct hyperplasia of the Malpighian bodies. The splenic pulp was not edematous, and the consistence of the organs was firm. Examination of the muscular structure of the bodies showed no gross alterations. Macroscopic examination of the bone marrow, likewise, showed no distinctive alterations.

Microscopic Examination.—Microscopic examination included the brain and cord membranes and the spinal cord at different levels; also the changes in the ganglion cells, interstitial changes in the cord, examination for the presence of hemorrhages and such changes as may occur in the pontine region, as well as microscopic examination of the internal viscera, the musculature, and bone marrow.

No distinctive changes could be observed in the dura. In the pia the changes were those of edema and inordinate venous engorgement, but without distinctive hemorrhage into the tissues. Minute examination of the pial meninges failed to show any distinctive microscopic alteration.

Membrane of the Cord.—In the milder cases of

the series the pia mater of the cord showed a normal histological picture, while in the more severe cases the blood vessels of the pia mater were the seat of a perivascular cell accumulation, often more marked in the cervical region, where the corresponding changes in the gray matter had occurred. At other levels the pia mater showed no extensive alteration. In those cases in which perivascular cell infiltration had occurred to a marked degree, the same perivascular infiltration had extended in and around the blood vessels in the ventral fissure. The character of these cells was that of a small, round mononuclear cell, having a round or oval nucleus, and looking not unlike a lymphocyte. No evidence of polymorphonuclear leucocytes was to be observed, but occasional plasma cells were seen mixed up with these mononuclear cells.

Cord.—Examination of the cords revealed varying pictures, when taken from different levels, from the cervical to the lumbar region. It is noteworthy that the more exaggerated pictures were confined to the cervical regions, and here the changes were of a variable character, and will be described under three heads: First, vascular changes; second, ganglion changes, and third, interstitial changes.

The vascular changes gave a varied picture in the cases examined, and at the levels where the lesion was most marked no distinctive microscopic hemorrhages were to be found. On the contrary, the more severe cases showed an engorgement of the blood vessels in the anterior horns and were regularly surrounded by collections of small, round mononuclear cells, sometimes six and eight rows deep. The lumina of the vessels were not impinged upon, despite the fact of excessive perivascular infiltration. The accumulation of these cells seemed to be in the adventitia of the blood vessels. The character of the cells was altered by pressure, as well as the nuclei. The nuclei were overstained and closely packed together. No polymorphonuclear leucocytes could be made out from a most minute examination.

A rather noteworthy microscopic appearance in a number of the cases examined was the island collection, apart from the blood vessels, of small round cells, closely packed together and replacing the gray matter at this point. Such island collections of cells were, at some levels, exceedingly numerous. The character of the cells was not unlike that of glia cells, and in the numerous sections examined it was quite evident that softening of the cord at such levels was occurring and had occurred at other levels in which distinct softening and vacuolation of the gray matter had occurred, leaving irregular round open spaces. These vacuolated spaces were of such microscopic character as to be readily distinguishable from artifacts of the nervous tissue. The character of the cells at different levels in the cases examined seemed to the writer to be that of a distinctive cell, which belongs to the glia type in such regions, resembling it in shape. Outside of the perivascular accumulations, apart from the tissue of the blood vessels on the aforesaid island glia accumulations, there were other cells which were mostly of a polyblastic character, in which the nuclei stained distinctly,

the outline of the cells being prominent but the protoplasm not taking on the eosin stain. In such sections the architecture of the horn, whether the lesions were unilateral or bilateral, was entirely lost and replaced by such accumulation of polyblastic cells. The cells, however, I consider only a variety of glia tissue. The microscopic changes had not only occurred in the anterior horns but were, in some cases at some levels, quite as extensive in the posterior horns.

Microscopic examination of the ganglion cells in the anterior horns at different levels showed all grades of degeneration from that of slight injury to entire disappearance of their nuclear and protoplasmic substance, leaving, in the areas most degenerated, well-staining ganglion cells showing a regular arrangement of their chromatic bodies. The microscopic study was closely confined to the ganglion cells at different areas, and in these there was found a degeneration of a very marked degree. The lesion in the ganglion cells from the cervical to the conus was marked by a degeneration of variable character, and involved not only the ganglion cells of the anterior horns but those of the posterior horns and throughout the dorsal cord of the columns of Clark as far down into the lumbosacral enlargement as the nucleus of Stilling. It was quite apparent, on account of the degenerations at different levels, that one might attempt a count of the ganglion cells in the various levels from the seventh cervical downwards, and to compare them with the approximated number of normal cells found therein one would find that the average number of normal cells left in the region most degenerated was about 10 per cent. Fully 90 per cent. showed the varying degrees of degeneration herein described. Nearly every grade of chromatolysis was observed, peripherally, centrally, and, in some places, perinuclearly. The predominating type was the well-known central chromatolysis so characteristically observed in axonal degeneration. In a great many of the cells (perhaps 40 per cent. of them) at regions most involved, the chromatolysis had advanced to a degree of complete loss of stainable substance, and even to complete cell destruction. The loss of nuclei of many cells was noted, only a shadowy outline of the cytoplasm, containing a light, granular-staining substance, being left. In other cells the nuclei seemed to be eccentric. This was the predominant condition in many of the sections examined at different levels in the most exaggerated areas of destruction. Eccentricity of nuclei, especially in the cells of Clark's column, with a central chromatolysis, was a prominent feature. Many of the cells, however, contained a fairly normal cytoplasmic staining of the reticulum of the cell, with lightly colored dustlike particles. No vacuolation of the cells at any level was observed. Marked degeneration in one horn as compared with the opposite horn of the several areas involved showed extreme destruction of the anterior horns on one side, with only a comparative lessening of the microscopic changes in the corresponding horn on the other side.

Changes in the cytotreticulum of the nucleus were manifest in most of the levels, though this part of the cell structure seems more resistant than the structures of the cytoplasm. There were, however,

no nucleolar variations or fragmentations occurring. Stress, however, must be made on the normal characteristic cells of Clark's column, it being well known that they contain fewer chromophilous bodies, and when such degenerations occur it is easy for one to misinterpret the lesions found in this column. When such extensive degenerations of the ganglion cells occur in the anterior horn there necessarily occur marked peripheral interstitial changes, cells which are variable in amount and in their microscopic character. The microscopic examination of the interstitial changes therein may be summarized as follows:

Interstitial Changes.—Here, again, the interstitial changes varied in proportion to the destructive lesions occurring in the ganglion, which were also marked at the different levels of the cord involved. These interstitial changes varied in amount from that of cell proliferation of small round cells to the most excessive accumulation of glia and polyblastic cells. In the milder degenerations the interstitial changes varied from a diffuse proliferation of small round glia cells to a perivascular involvement of the blood vessels in the anterior horn and an extensive replacement of the anterior horns by excessive island accumulations of small round plasmoid or polyblastic cells, as well as to extreme replacement of the whole anterior horn, either unilateral or bilateral, with characteristic cells belonging to the glia type. The mononuclear cells around the blood vessels seemed beyond the adventitia, and, though variable in amount, had little or nothing to do with the occlusion of the vessels therein, though the cells themselves were altered by pressure. The island accumulation of glia cells, with their dark-staining nuclei, was a characteristic feature in a number of the levels examined in the more severe cases, and it could be made out that such cells were in the process of disintegration, leaving a tissue light in structure and evidently disintegrated, in places leaving vacuolated areas in the different levels of the anterior horn. Such microscopic changes were not, however, noted in the posterior horn. In some regions of the cord an entire replacement of the ganglion cells was apparent. There was a replacement by accumulations of coalescent cells, polyblastic in type, but of evident neuroglial origin. These cells were especially abundant in some areas, but were absent in others. The interstitial changes in the posterior horns were notably diminished, as compared to the changes in the anterior horns. No evidence of leucocytic infiltration was observed in any of the sections examined from both areas.

Hemorrhage.—Microscopic examination of sections from many different levels showed a complete absence of hemorrhage. The blood vessels in the anterior horns in many sections were enormously distended with a perivascular unsheathing of lymphoid cells, but in no wise diminishing or compressing the lumen. Rather curious pictures were observed in the adventitia of the blood vessels of the white matter of the cords throughout, the blood vessels having been pressed off to one side, leaving a clear-staining area, which, with thionin stain, gave a blue appearing substance. This I consider an edema in the perivascular sheath, but it has little or no significance. There were no noteworthy changes in the white matter of the cords at differ-

ent levels. The varied changes noted by other observers are not in keeping with the present findings, it having been reliably established that focal cellular accumulations in relation to the blood vessels have occurred in some cases, but which are notably absent in others, and is of minor importance.

The changes in the pons in those lesions giving clinical pontine symptoms are of the same microscopic character as those described in the cord of the case of Dr. Carr, referred to above, varying in relation to the intensity of the disease. Microscopic examination of the posterior nerve roots at different levels showed, in some cases, lightened areas, which seemed to the writer to be focal areas of degeneration. These were of such variable character, however, that no great importance can be attached thereto.

Examination of the peripheral nerves in those cases showing paralysis of the extremities were made by osmic acid, and fresh teased specimens of such nerves observed. The variability of the degeneration of the myelin in the cases of long standing showed degeneration of the nerve fiber with fragmentation of the myelin, and the heaping together of round, black globules stained by osmic acid. Microscopic examination by Marchi's method of such nerve fibers has, as yet, not been completed, but it is evident from examination of such "teased" nerves that more convincing results will be observed of such degeneration.

Microscopic examination of sections of the viscera proved negative, except where macroscopic changes had occurred in the gastrointestinal canal, the mesenteric lymph nodules, and the spleen. In a number of cases examined by other observers the liver was said to be the seat of focal accumulations, replacing the liver cells in that area in and around the vicinity of the central vein, the cell making up this focal necrotic zone being reticular in type and containing many dust-like granules of nuclear material. Such microscopic changes in the liver are difficult to find.

The microscopic examination of the mesenteric lymph nodes showed a characteristic hyperplasia with edema and congestion of lymphatic structure. The perilymph sinuses were distended with large vacuolated cells containing debris. Injection of the blood vessels was well marked and the lymph nodules as a whole markedly hyperplastic. The same alterations of a hyperplastic nature were made out in the solitary lymph nodules in the colon, and also in Peyer's patches in the small intestine throughout, giving a characteristic microscopic appearance of intense hyperplasia. No noteworthy changes were observed in the kidneys, except for an early parenchymatous swelling of the tubules.

Examination of different areas of the brain and meninges and spinal cord and meninges at different levels, appropriately stained for organisms, gave consistently negative results.

First Description of Test for Biliary Acids in the Urine.—According to Ebstein, Tiedemann and Gmelin did not originate this test, as is commonly asserted. In 1787 Marabelli of Pavia preceded them by 35 years in the use of nitric acid for this reaction.—*Nederlandsch Tijdschrift voor Geneeskunde.*

MENTAL DISEASE.

By JOSEPH SMITH, M.D.,

BROOKLYN, NEW YORK.

PHYSICIAN TO THE BROOKLYN STATE HOSPITAL.

INSANITY presents so many problems, it can be approached from so many directions, that for a time I did not know which particular problem to select for discussion this evening. Some of you may be interested most to hear how a violent maniac is dealt with in a hospital, others would prefer a description of the daily routine life of the insane in institutions. Such matters, while undoubtedly of engrossing interest, are far inferior to the more general questions, such as: what are the known causes of insanities; how may insanity be prevented; and how do organized institutions attempt to deal with their inmates? And first, let me define to you the term insanity. What constitutes normal mentality allows of considerable latitude of application, and there is no standard which will enable us to differentiate the normal from the abnormal. However, though the borderline separating the two is ill-defined and often difficult to determine, for practical purposes one may assume that, barring individual peculiarities, one's mental condition is abnormal when his conduct attracts attention by reason of its peculiarity or queerness, when thought becomes illogical, or when emotional instability is so marked as to be out of all reasonable control, and especially when this emotional instability is disproportionate to the magnitude of the exciting cause. For instance, it is quite normal to feel temporarily depressed over the loss of a parent or child, but when the depression deepens with the passing of time, instead of fading, and refuses to be influenced by common-sense methods, then it evidently has passed the bounds of normal mentality. As you know, the law absolves the insane from the consequences of their acts, and in any case of crime it requires proof that the person who committed the act did not know the quality or nature of the act in order to declare him not responsible. But anyone committing a crime under the influence of strong, irrepressible emotions is not necessarily insane, and if his mind clears up shortly after the act he should generally be held strictly accountable. Insanities do not suddenly flare up and vanish in a day or two. Where mental disturbances are of such brief duration, they are usually produced by toxins or poisons elaborated during the course of infective or exhaustive conditions. Thus, temporary mental derangement may occur during typhoid fever, pneumonia, and the like, or follow prolonged exhaustion, fatigue, etc. In deciding the question of insanity attention should be paid to the intellectual standard of the individual in health. Thus, a defect of logic in the conversation of an educated person would be far more indicative of mental derangement than a similar defect in one whose powers of reasoning have never been adequately developed.

Broadly speaking, we recognize two kinds of insanities: (1) Those resulting from definite morbid changes in the central nervous system and

spoken of as *organic*; and (2) those in which no such evident changes are observable; these latter are called *functional*. Among the first we may mention the alcoholic insanities resulting from prolonged abuse of alcoholic stimulants; the temporary and permanent mental disturbances caused by the poisons of morphine and cocaine; the insanities due to syphilis, acquired or hereditary; the mental disorders consequent upon arteriosclerosis, or hardening of the arteries of the brain and giving rise to softening of various brain areas or to hemorrhages. The usual physiological shrinkage of the brain in the old may be of such severity as to give rise to various mental defects, notably marked loss of memory, confusion, etc. Likewise, injuries to the brain, such as result from blows or falls, may give rise to permanent mental symptoms.

Among the functional mental disturbances we reckon the maniacal cases, the various depressive or melancholic states, and what is known as adolescent insanity or dementia precox. This latter form occurs in the young at the age of twenty or thereabout, and leads to a gradual mental deterioration, which is permanent. These patients form about 10 or 15 per cent. of the total admissions to institutions. As a group, the functional psychoses are among the most interesting we have to deal with and the solution of the many problems they present, such as their causes, the mechanism of their manifestations and the possibilities of their arrest, have attracted the attention of the best minds of the profession. The studies which have been made in these cases have enlightened us as to the manner in which these diseases arise, have given us a psychological interpretation of many of the phenomena they present, but I am not going into a discussion of these interesting problems as they lie outside of your immediate interests. Suffice it to say that the results of their investigation have been most promising and that at present we possess a clearer comprehension of the insane utterances, a truer appreciation of the motives which guide the patients in their various activities, and hope is thus held out that eventually a cure may be found for these unfortunates.

From the foregoing you will easily comprehend that many mental diseases are preventable. Thus, if alcohol could be eliminated from the daily life of a large percentage of our population, the alcoholic insanities, of which there are several varieties, would disappear. Likewise, when in some future date syphilis will become a disease of the past, the various mental diseases which are directly traceable to it as a cause will disappear; and since heredity plays a prominent rôle in the functional psychoses, better eugenic marriages will result in offspring not burdened with hereditary predisposition. In what subtle ways heredity works we do not know, but the characteristics of the offspring lie in the parental germ-plasm. Those of you who are acquainted with the theories of heredity promulgated by Weissmann and the laws of heredity as discovered by Mendel will easily know what I mean. Much can be done to safeguard the child from harmful influences which may culminate later in a mental disease.

*Read by invitation before the Bensonhurst Literary Circle, January 23, 1918.

Those already hereditarily predisposed should have their occupations chosen with care, their daily life well regulated, exciting or depressing accidents removed from their path, and their sexual development carefully watched and supervised, since most psychoses of the functional order begin at the age of puberty or thereabouts, when the boy or girl becomes conscious of new feelings, desires, fancies, etc. Analyses of many cases have shown that it is at the threshold of adolescent sexual life that hopes and aspirations, desires and longings meet their shipwreck. People who are prone to become insane show their incapacity to adjust themselves to the new situation. I could adduce abundant evidence to justify my statements but for lack of time will cite an instance or two. A girl who has been brought up without the least knowledge of things sexual gets married—her first sexual experience upsets her; the next day she breaks out into a violent excitement and passes through a mental attack lasting months. Another patient placed in a similar situation becomes apprehensive, loses her appetite, conceives a dislike for her husband, whom she in reality loves, leaves him, and returns to her mother's home. Evidently we have to do here with a disturbance of emotional equilibrium brought on by a sudden change in the sexual life. From these considerations it is plain that sex education is of prime importance at an age when such questions begin to agitate young people. The late Professor Münsterberg, some of you may remember, opposed the instruction of young women in sex matters on the ground that their innocence and finer feelings are thus outraged and that premature knowledge of that mysterious expectancy which like a halo envelops the whole subject, results in disillusionment, but I fail to see the disadvantages he mentions. I do not believe that knowledge of sex problems can have any deleterious effect on young people. It will not tend to rob courtship of its sweetness nor will the young woman thereby lose anything of that innocence of which she can justly be proud. Sex problems have never received as much attention as of late. Since the publication of Prof. Sigmund Freud's works on hysteria and allied conditions, and especially since the appearance of his book on "Dream Analysis," our interest in this phase of life has been quickened and at present it forms the battle ground for many opposing theories and heated discussions. Much opposition to Freud's views has sprung up which undoubtedly is partly due to overzealous disciples who saw sexuality lurking in every thought and act. The conservative view is that Freud has made a really valuable contribution to our knowledge of the fundamental instincts and emotions and pointed out the tremendous rôle sexuality in all its aspects plays in our daily life. The Poet Schiller said that love and hunger are the mainsprings of our life, and in our day when the struggle for existence is not as acute as in primitive humanity, sexuality claims the greater attention.

So far I have been limiting myself to a discussion of general problems and I am sure many of you would wish that I restrict my talk on generalities and take up some definite concrete every-

day experiences with the insane. So I will try briefly to introduce you to several mental disturbances and some of their salient manifestations. The maniacal cases will claim our attention first, chiefly because they are recovered from and on account of their tendency to recur. They generally begin abruptly, are characterized by a happy mood and hyperactivity, talkativeness, etc. Typical cases are diagnosed by the expert at a glance. After a period of several months the excitement abates and they begin to convalesce. In the majority of cases there is an hereditary predisposition. During their excitement they are apt to tear, destroy, and assault, denude themselves, etc. When the excitement is excessive we combat it by immersing the patient in a continuous bath where he may remain for weeks. It is remarkable how a violent patient will quiet down after remaining in the tub a few hours.

There is a form of insanity occurring generally in young people, the initial symptom of which is a depression. Gradually the depression becomes more pronounced, the patients are dejected, refuse to eat or to dress, and the condition may culminate in cessation of all activity. They become mute, have to be forcibly fed, they are dirty in their habits, and may attempt suicide. Such patients usually get well, though there is great likelihood of recurrence, either a similar attack or a state of excitement following. The treatment consists in careful nursing and general supervision. They have to be guarded against all possible means of self-destruction. As soon as these patients become accessible to external influence an investigation is begun into the upsetting causes, his doubts and fears are made a subject of discussion, and his delusions are corrected by argumentation, etc.

There is a form of depression occurring at the age of 50 or 60, a period which women speak of as the change of life. In men this change occurs at a later age. It is a period when people begin to feel that they are getting old, that their mental and physical powers have passed the zenith. They begin to take a retrospect of their lives, a sort of striking a balance of their deeds, and if one's labors have not been crowned with success a peculiar mental state supervenes. They get anxious, fear they will come to want, will never get well; have lost their bodily organs. If religiously inclined, they imagine God has forsaken them, their souls are eternally doomed; they have committed sins, crimes, etc. This mental state has been termed *Involuntio melancholia*. In the majority of cases it is a hopeless condition, mainly because it occurs at a period of life bordering on old age and the patients frequently suffer from real bodily ailments, notably heart and kidney disease, asthma, etc.

Several varieties of mental disturbances occur as a result of alcoholic excesses; I may mention delirium tremens, which follows alcoholic debauch and is characterized by vivid hallucinations of sight, often of a terrifying character. Furthermore, alcohol may give rise to chronic delusional states, dementia, failure of memory, and neuritis. The chief syphilitic disorder affecting the mind is paresis, a truly terri-

ble disease. It comes on after years of infection, when all signs and symptoms of the original trouble have disappeared; it presents a varied mental picture and is hopeless. I could give you many interesting details of this disease but time forbids going into it minutely. Among the insane we meet with a class called paranoiacs, who are distinguished by their harboring all sorts of delusions. You know a delusion is a fixed idea which resists all attempt at correction. The behavior and outward appearance of these patients present nothing abnormal and their memory is excellent. As a class they present the most difficult problem and in the greatest majority of cases it is a thankless job to try to correct their false ideas. In a few cases, however, improvement or even cure has been accomplished.

The treatment of the insane is mainly a psychological problem and a thorough understanding of the difficulties the patient is laboring under is essential to success. The patient should never be looked upon as an object of amusement; his fears, wishes, and complaints should be met with in all seriousness, and an effort should be made to establish friendly relations with him—only then is it possible to gain his cooperation and good-will and lead him to the appreciation that one is really interested in him, and the way is smoothed to effectual cure. It thus explains how a physician is able to quiet down a violent patient by a few kindly and appropriate words when the whole personnel of the ward were exerting themselves ineffectually to their utmost to subdue him.

The great bulk of the population of the hospitals is made up of chronic cases. They constitute about 70 to 75 per cent. of the inmates. Many are employed in various way—they work in shops, stores, assist in the wards, etc. Various amusements are provided for them—dances, moving pictures, and vaudeville performances. It is a queer motley crowd that meets one's eye when going through the wards of an insane asylum. Here you encounter the flotsam and jetsam of the population of a big city—the ignorant, the criminally inclined, the indolent. Here, also, you see the educated, the professional man, the business man who worked hard all his life, and the promising youth whose usefulness was prematurely cut off. These unfortunates shared our joys and sorrows, the emotions agitating us were once part of their mental life—a good many still retain fond impressions of earlier days, but they are often distorted, transposed, and do not harmonize with the individual's present state. It is a depressing picture I am painting to you, but all the more one's contentment will be greater when realizing that amidst the trials and tribulations of modern life he has been able to keep sound his most precious gift of nature—the mind.

War Amenorrhea.—The journal literature of this subject, although considerable, has added little to our knowledge. Spaeth has shown by measurements that the cavum uteri is on an average 5 to 7 cm. long. Stickel states that in the Berlin Charité the percentage of cases has risen steadily from 1 to 7.—*Correspondenz-Blatt für Schweizer Aerzte*.

A CASE OF BILATERAL TOTAL OPHTHALMO- PLEGIA.*

By ALFRED WIENER, M.D.,

NEW YORK.

THE occurrence of total bilateral ophthalmoplegia in the latter years of life is rare, and offers some difficulties when considered from a differential diagnostic standpoint. The following is the record of such a condition in a patient who presented himself to my notice a short time ago:

M. P. is sixty-seven years old. He was admitted to St. Luke's Hospital with the following history: In the latter part of November, 1917, he was taken ill with an attack of influenza. Within ten days he was able to get about. He was on his way to his place of business when suddenly his eyes began to give him discomfort. He became dizzy and fell to the sidewalk. He did not lose consciousness, as he was able to get up without assistance and return home alone. His family physician was called, recognized the gravity of the symptoms, and sent him to the hospital.

An examination of the patient brought out the following facts: He had never been ill with any nervous disease; in fact, he does not remember when he had been ill or confined to his home. His family history is without significance.

The objective examination at the time of his entrance into the hospital was the following: His mentality was good. There were no painful spots to percussion or pressure over his skull. He was not suffering from any headache or vertigo. The vision of the right eye was 20/70th and with a sphere +2.50 it equaled 20/30ths. The vision of the left eye was 20/40ths and with a sphere +2.25 it equaled 20/20ths. With a plus 3.25 sphere added he read Jaeger one at 15 inches.

There was present a total ophthalmoplegia in both eyes. They occupied the median position. Not the slightest movement was evident. The pupils were widely dilated and there was no response to light, accommodation, or consensual reaction. The ptosis was a little more marked on the right side than on the left. An ophthalmoscopic examination revealed a sclerosis of the lens in both eyes, and some peripheral opacities in the left. The fundi in both eyes gave evidence of arteriosclerotic changes. The fields were normal. There was no involvement of any of the other cranial nerves, nor was there any paresis or paralysis present in any other part of the body. The physical examination showed a blood pressure of 170 and an accentuated second sound of the heart. The larger arteries showed evidence of an arteriosclerosis. There was also a mild interstitial nephritis. Alcoholism and syphilis were denied; syphilis was, furthermore, ruled out by the various tests which were made. There has been a gradual return to power of the various external muscles which were affected. At the last examination there was a slight response of the pupil to convergence, but not to light. It is possible now to get action downward, inward, slightly outward, and upward. It should be mentioned that as the power returned it did so in the corresponding muscles of each eye.

Résumé.—We have a patient sixty-seven years of age, with arteriosclerosis and a mild interstitial nephritis. He develops an attack of influenza, and directly thereafter a sudden bilateral total ophthalmoplegia. It is a well-known fact that through the toxin of grippe infection both functional and degenerative changes may occur in the motor nuclei of the third and fourth ventricles. Especially to become involved are the various groups and combinations of eye muscles, resulting in a partial or complete ophthalmoplegia. At the present time there is very little anatomical evidence to determine

*Presented at a meeting of the Ophthalmological Section of the New York Academy of Medicine, January, 1918.

whether such paralyzes occurring after infection are due to a functional toxic, or an inflammatory degenerative change in the nuclei or nerves. A second characteristic of influenza and other infections, although rare, is the thrombotic closure of some of the larger blood-vessels. The cause and method of origin of such closure in arteries varies. Some authors speak of a grippe arteritis, others of an embolism. Such an embolism may occur, for instance, in a case where there is present an arteriosclerosis and at the same time an acute or chronic endocarditis. Again, where such gross disturbances cannot be demonstrated, a thrombus may arise from the left side of the heart and get into the circulation. It may happen incidentally that with an obliterating arteritis of the arteriosclerotic type an arterial thrombus takes place through the weakening influence of an influenza upon the heart and blood vessels. In still other cases a primary or spontaneous thrombus may occur.

In this patient the sudden onset certainly speaks for a vascular lesion. To my mind it hardly seems possible that an acute inflammatory or degenerative process would suddenly produce such an extensive paralysis. The "polioencephalitis" types, which one would naturally think of in a case like the above, would involve the muscles in groups, and irregularly. Such an extensive paralysis as was present in this case would prove rapidly fatal by extension to the medulla.

A blocking up of the basilar artery at its upper end will account for the above clinical picture. It may have been an embolism or a thrombus; either lesion is a possibility. In the absence of any heart lesion I am inclined to believe that a thrombus occurring in such an artery with an obliterating arteritis of the arteriosclerotic type, indirectly produced by a grippe infection, can be held responsible for the symptoms in this patient. The prognosis in these cases is good, as I have had occasion to learn in two others of a similar nature. A collateral circulation probably establishes itself through the circle of Willis.

One other explanation might be offered for the occurrence of this paralysis. If we wish to believe that a toxic agent circulating in the blood may abolish function without visible changes, such an opinion is entitled to respect, but it hardly seems plausible.

550 PARK AVENUE.

Medicolegal Notes.

Proximate Cause of Death.—In proceedings for compensation under the New York Workmen's Compensation Act the State Industrial Commission found as conclusions of fact that on the 28th day of February, 1916, while the deceased was doing some heavy lifting under a boiler, and in consequence thereof, he received an injury which resulted in a right inguinal hernia; that after an examination by Dr. Fisher, a physician provided by the insurance carrier, an operation was performed by him on account of the hernia about March 19, 1916; that "the deceased made a fair recovery from the operation, the wound having healed by primary intention, and the patient was able to be about, for a time, although in a weakened condition," and that six weeks after the operation his condition became such that he had to take to his bed, and he died April 26, 1916.

The Commission also found that at the time of the operation, and for some time prior thereto, the deceased suffered with chronic myocarditis arteriosclerosis, which condition contraindicated the operation and

the anesthetic administered therewith; that the operation and the anesthetic so weakened and debilitated deceased as to light up and hasten his previously diseased cardiac condition to a fatal close, and that "the injuries which resulted in the death of John Tucillo were accidental injuries, and arose out of and in the course of his employment."

The employer and insurer appealed. They contended that the facts found were not supported by the evidence in so far as they relate to the cause of death. It was held that the proof failed to support the theory that the hernia accelerated or aggravated the cardiac condition of the deceased, or that it was the direct cause of the death. All the evidence in the case negated that idea. The evidence also failed to show that the operation or the anesthesia hastened his death.

There was much testimony given before the Commission as to the condition of the deceased before and after the operation, but neither of the two attending physicians nor any one of the four other physicians, called by the insurance carrier to testify as experts, was willing to express the opinion that the operation or the anesthesia was the cause of death, or that the deceased would not have died of myocarditis the time he did if the operation had not been performed. On the other hand, two of them testified that they did not think the operation or the anesthesia accentuated or accelerated the disease or hastened the death of the decedent. Dr. Levy, in his first report to the Commission, said:

"It is very difficult to state whether the operation for the hernia had debilitated claimant to such an extent that the latent pathological conditions of the heart, and blood vessels have been actually exacerbated and thereby have caused premature death."

—and in his second report that:

"I am not able to consider that death was caused either by a hernia nor in consequence of the operation."

Subdivision 8 of section 3 provides that:

"Death when mentioned as a basis for the right to compensation, means only death resulting from such injury."

To establish the fact that a death resulted from an injury, it is clearly not sufficient to prove that the person received the injury; that an operation was performed on account thereof, and after he had apparently recovered from the effect of the operation and the anaesthesia he died from a disease that existed before the injury. The award was for these reasons reversed and the case dismissed.—*Tucilla v. Ward Baking Co.*, New York Appellate Division, 167 N. Y. Supp. 666.

"Accidental" Means of Injury and Death.—The Circuit Court of Appeals, Third Circuit, holds that under a policy insuring against injury or death effected through external, violent or accidental means, the means or cause of death must be accidental, and it is not enough that the death itself is accidental, in the sense of being unintended, unexpected, or unforeseen. The word "accidental" means happening or coming by chance or without design. A butcher, insured against death by accidental means, having a boil on his neck, rubbed it while engaged in cleaning chickens. He broke the scab, permitting germs of erysipelas to enter, and he subsequently died of that disease. It is held that his death did not result from accidental means, as the breaking of the scab was a probable result, and one reasonably to be expected from his intentional act.—*Maryland Casualty Co. vs. Spitz*, 246 Fed. 817.

Action for Medical Examiner's Salary.—In an action against an insurance company for compensation for services as medical examiner, there was evidence tending to show that under the plaintiff's appointment he was to be paid \$60 a month, and other evidence tending to show that this salary was to apply only to a certain kind of insurance for a limited period of time. This evidence, however, was not conclusive, and the whole evidence was susceptible of a construction in favor of the plaintiff. It was held that a case was presented where different inferences might reasonably be drawn from the evidence by persons equally fair and reasonable, and the appellate court refused to disturb the judgment for the plaintiff for want of evidence to support the verdict.—*Liberal Life Assur. Co. vs. Cook* (Ind.) 118 N. E. 586.

Military Medicine.

Hospital Treatment of Shell Shock.—In *Recalled to Life*, No. 2, is an address by Lieut.-Col. Aldren Turner, C. B. M. D., in which he discusses the principles of the management of the shell shocked and neurasthenic soldiers in the special military hospitals. These principles, four in number, were laid down early in the war, but they were subject to modification as our knowledge of these patients and of their disabilities became better known and understood. The first principle was segregation. For the most part the neurasthenic soldiers had been treated in institutions specially set apart for the purpose under the care of medical officers specially qualified to treat them. The adverse criticisms which were brought forward in opposition to segregation in the early months of the war had not been justified. On the contrary, its usefulness had been strengthened and extended by experience. These patients did not imitate each other, or in other ways react harmfully upon each other. On the other hand, it has been found that when placed in the general wards of a hospital, the sufferer from shell shock not infrequently was the butt of the other patients, who were unsympathetic and disposed to regard as trivial the tremors, stuttering speech, unnatural gait, and other symptoms which characterized so many cases of shell shock. The admixture of these patients, as had been suggested with cheery companions, suffering from non-nervous disabilities, might even be undesirable.

The second principle was to give the medical officers liberty to treat their neurasthenic patients along such lines as they considered desirable and which experience had shown to be of therapeutic value. There was no disorder to which the axiom "treat the patient and not the disease" applied with greater directness than to neurasthenia. This liberty of action was very necessary when they considered the different types of neuroses and psychoses which were admitted to the military hospitals under the guise of shell shock. Cases of exhaustion required rest in bed; paralytic cases required exercise and reeducation of the movements of the paralyzed limbs. The simpler forms of anxiety needed reassuring and explanation of the origin of their fears. The terrifying dreams which disturbed the sleep of so many men suffering from shell shock required to be analyzed and explained. The dreads and fears, delusions and hallucinations, and other morbid ideas required to be searched, investigated and understood. After this the readjustment of the patient's mental outlook towards his symptoms required to be taken in hand. It had been found that a too constant and too frequent use of massage, of electrical applications, of baths, and of other physical methods of treatment assiduously practised at the spas, tended to accentuate rather than relieve the condition for which they were used.

The third principle was occupation, quite a number of cases of war neurasthenia and genuine shell shock in the early stages derived great benefit from a "rest cure," but it had become increasingly obvious, with more experience and knowledge of

these cases and their causes, that rest and isolation had only a limited application. The best results were obtained by a judicious combination of a suitable psychotherapy and occupation, mainly of an outdoor kind. It was useless to attempt to cure by work alone, a man whose mind was depressed by anxiety and forebodings attributable to circumstances which he did not understand; but if by judiciously selected work and carefully regulated outdoor occupation, his sleeplessness was mitigated and his circulation and general nutrition improved, the value of the mental therapeutics was enhanced and supplemented.

The fourth principle was compensation. It was recognized early in the war that a large number of soldiers who suffered from shell shock and neurasthenia, would be unfit to return to military duty, although their ability to carry on their civilian work after discharge would not be more than temporarily impaired. As it had been recognized for a long time that some forms of nervous disability were prone to exaggeration, or might even be made chronic by undue consideration, it was determined that nothing should be done by the payment of pensions which would retard or prevent the recovery of soldiers who had been disabled from nervous breakdown. It was thought, therefore, to be desirable to recommend the granting of a money bonus, in place of a pension to selected cases of neurasthenia and functional nervous disorder occurring amongst soldiers when treatment in hospital was no longer necessary and the patient was unlikely to be fit for further military service.

Gunshot Wounds of the Head.—Captain H. E. Gamlen, R. A. M. C., and Captain S. Smith, R. A. M. C., writing in the *Archives of Radiology and Electrotherapy* for February, say that previous to the introduction of the helmet simple fractures of the skull, as shown by the x-rays, could be safely left without surgical interference, and they never had reason to regret an expectant policy; but lately they have been struck by a remarkable series of cases of wounds on or about the apex of the temporal crest. These patients came in but little affected, often showing no physical signs or at most a slight facial weakness, paresis of one arm, or some aphasia. Their temperature and general condition on admission gave no cause for anxiety. The men remained well for two or three days, at the end of which time signs of cerebral mischief suddenly revealed themselves. Convulsions unamenable to bromide or morphine, increasing optic neuritis, severe headache progressing to drowsiness, with progression of focal symptoms all indicated urgent need for operation. On turning down a flap, at most a slight cracking of the temporal bone could be seen; more commonly there was a considerable area of discoloration, a bluish appearance of the bone under the wound; in one case there was no change in the bone at all. There was no extensive extradural hemorrhage, but the dura was in most cases adherent to the subjacent brain by a layer of altered clot. A considerable cavity containing pulped brain and sanguineous material was found in the temporal lobe. Evacuation of this collection with drainage caused a gradual amelioration of symptoms

and their mortality for six cases has been nil.

A Clinical Study of Some Pyogenic Lesions Observed in France.—Captain W. H. Brown, R. A. M. C., writes in the *British Journal of Dermatology and Syphilis* for December, 1917, concerning some pyogenic lesions observed in France. It is a well-recognized fact, he says, that during war times new disease conditions arise with which we are unfamiliar and that known conditions alter in type and character. The change is most probably due to the altered conditions of life; the physical and mental strain which must necessarily tax the resisting powers of the body to the utmost. This applies in the domain of dermatology as in the diseases of the other systems. For example, there is an intractable type of seborrhea corporis et capitis subject to frequent relapses with secondary pyogenic infection; there is the unusual complication of adenitis of the groin in scabies when there is no secondary infection to account for it; there are various types of impetigo which present features not commonly seen in civil life. The type of infection Brown confines himself to is the streptococcal condition so commonly met on the buttocks and lower limbs, a type which causes a great deal of destruction of tissue and which is a great source of wastage to the army. It is a form of impetigo which requires to be clearly differentiated from the milder condition met with so frequently on the face and head, though both are of streptococcal origin. The difference may be partly explained by the situation on the lower limbs and the consequent much greater exposure to irritability by dirt and perspiration. Brown gives a minute and exhaustive description of the clinical manifestations of the infection and points out that in the callous ulcer stage these cases are often sent into hospitals diagnosed "syphilis." There is never, however, any of the serpiginous character in the treated ulcers such as is found in the old tertiary syphilitics. It is not to be inferred that all the lesions go to the formation of large callous ulcers. There are all stages and degrees of the infective process, but the primary pustule is the same and a culture from these early lesions gives a pure growth of streptococcus; also the superficial type of impetigo may be present at one and the same time on the limbs. Relapses are frequent. It is not uncommon for patients to be returned to the hospital within one or two weeks with fresh sores, or a patient will be discharged to duty from one hospital; after six to eight weeks' treatment only to be readmitted to another within a very few days. The wastage to the army may amount to four months or more in some cases. Frequently those men stated that it was the wearing of puttees which precipitated each attack. From the frequency with which pure streptococci growths were obtained from these pustules on different media there appears little doubt that the lesion is primarily due to the streptococcus. In the larger lesions very often the streptococcal growth was contaminated by staphylococci *albus* et *aureus*. The latter sometimes quite outgrew and obliterated any possible trace of the streptococcus. The *Bacillus pyocyaneus* was found in a few of the large sores. To

what extent the secondary staphylococcal infection takes part in the destructive process is a little difficult to say, but doubtless it plays an important part. Rare staphylococcal conditions, boils, and folliculitis frequently complicate the condition and add greatly to the difficulty of treatment and the duration in hospital. Wassermann tests were made in all cases with negative results, also the edges of the sore were scraped and the serum examined under ground illumination with negative results. There was no question of the ulcers being of varicose origin. As regards treatment, one can emphatically lay stress on the great importance of rest in bed in all acute cases or in those with any degree of ulceration. Treatment was often ineffectual until the patients were put to bed. Even comparatively trivial cases would sometimes require rest in bed before healing took place. The essentials in local treatment were the perfect cleaning of the sores and dressing twice daily if possible. Almost every application was tried, including scarlet red, brilliant green lotion and ointment. The most satisfactory applications were a 20 to 30 per cent. ichthyol ointment containing one-sixth per cent. perchloride of mercury, bismuth, iodoform paraffin paste, red lotion, easol and boric fomentations. Each had its own place and use. Scarlet red and brilliant green were only useful when the sores were fairly clean and even then gave no better results than the other things properly applied. Strapping the callous ulcer with boric acid powder gave excellent results.

New York Hospitals Open Clinics to Naval Medical Officers.—Upon the recommendation of commanding and medical officers of certain ships of the Cruiser and Transport Force, United States Atlantic Fleet, the Commander of the Cruiser Force has sought and obtained through the Mayor's Committee on National Defense access to the clinics of hospitals of Greater New York in order to give the medical officers of the cruisers and naval transports opportunity for increasing their professional experience. Thus far the following hospitals have tendered their services: Mount Sinai, Bellevue and the Allied Hospitals, Beth Israel, New York Eye and Ear Infirmary, Hahnemann, Italian, Long Island College, Dispensary and Hospital for Deformities and Joint Diseases, New York Orthopedic, New York Polyclinic, Ruptured and Crippled, New York Ophthalmic, New York, Park, Lincoln, Willard Parker, Memorial, St. John's Guild Floating Hospital, and the Herman Knapp Memorial Eye Hospital. The only formality required will be the presentation of the officer's personal card to the office of the superintendent of the institution upon occasion of the first visit. Daily information can be obtained of operations, hours, and operators at the various hospitals in Greater New York from the Society for the Advancement of Clinical Study in New York, Bureau of Clinical Information, New York Academy of Medicine.

The Training of Nurses' Aids.—The Mayor's Committee on Hospital and Medical Facilities of New York City recently instituted an inquiry for the purpose of ascertaining what preparations the

hospitals of the city were making to effect the shifting of graduate nurses from civil to military practice and to provide against other contingencies in the nursing field arising out of the war. The investigation shows that efforts to enlarge the training schools have not yielded satisfactory results. There is a growing conviction that the nursing crisis can be met promptly and effectually only by the training of a large number of volunteer nurses' aids. Hospitals in New York City which have undertaken the training of nurses' aids are Bellevue, Brooklyn, German, Mount Sinai, Post Graduate, Presbyterian, Roosevelt, St. Luke's, and the Staten Island. Reports from these institutions show that a total of 411 aids have completed their theoretical and practical training. A number of the larger hospitals of the city are now employing nurses' aids. The committee recommends that the plan for the training of volunteer nurses' aids now followed in base hospitals under the auspices of the Red Cross Nursing Service be accepted and extended to such other hospitals as may be approved by the Red Cross for the purpose, and that such courses whenever given should conform substantially to this plan and be carried on under the same auspices. Dr. S. S. Goldwater, chairman of the Mayor's Committee on Hospitals and Medical Facilities, says the time has come for the training of volunteer nurses' aids in large numbers and for increasing by every possible means the number of regularly enrolled pupil nurses in view of the fact that the hospitals of the country, both civil and military, will doubtless, within the next two years, be called upon to care for 150,000 additional patients.

Two New York City Hospitals for Government.—As the result of a conference between representatives of the Federal Government and Mayor Hylan, the Sea View Hospital on Staten Island and the Otisville Sanatorium at Otisville, N. Y., will be taken over by the Government. The Government plans to expend about \$450,000 in providing additional wards and beds and in making other improvements. It is planned to use these hospitals jointly for both wounded soldiers and city patients.

New York Hotels for Nurses.—The United States Government has designated ten hotels owned and operated by the Knott Brothers for the care of Red Cross nurses who come from various parts of the country and have to remain for a time in New York before leaving for the other side. These hotels have been selected because of their convenience to steamship piers and because some have been designated as base hospitals and replacement stations.

Sick and Disabled Soldiers Brought Home.—An American transport arrived at the Port of New York on April 17 with 2,000 soldiers and sailors said to be recuperating from illness or from wounds received in battle. Secrecy has thus far been preserved regarding the disposition of these invalided men.

New York Doctors Get War Crosses.—Lieutenant George Patton of the American Army Medical Corps has been awarded the French War Cross for courage in treating wounded men while without a gas mask during a heavy bombardment of

gas shells. He continued to work until overcome by gas. Lieutenant Theodore Higgins Sweetser, M. R. C., U. S. A., has been recommended for the British Military Cross for conspicuous gallantry and devotion to duty in having rendered valuable assistance to more than forty men suffering from gas while he was also suffering from its effects.

Died in the Service.—Captain HARRY JAMES O'BRYAN, M.R.C., of Watertown, S. D., a graduate of Barnes Medical College, St. Louis, Mo., in 1902, died at Fort Snelling, Minneapolis, on April 3, aged 40 years.

Lieutenant ARTHUR LEWIS BOBRICK, M.R.C., died of pneumonia at the Harlem Hospital in this city, at the age of 26 years. He was a graduate of the Long Island College Hospital Medical School in 1917 and had served on the staff of the Harlem Hospital, being also a member of the faculty of the New York School of Medical Gymnastics and Massage.

Lieutenant WILLIAM T. NAGLE, M.R.C., formerly practising in Fairfield, Conn., has been killed by an accident on the front in France. Dr. Nagle was born in 1872 and was a graduate of the Medico-Chirurgical College, Philadelphia, in 1914, serving later as interne at St. Raphael's Hospital in New Haven.

Philadelphia Doctors Wounded on Western Front.—A despatch from London, under date of April 10, states that in the course of the recent fighting a surgical team, sent to a casualty clearing station by a Philadelphia hospital, was heavily bombed. Dr. Edward B. Hodges, Dr. Henry Dillard, Jr., and Miss Isabella Stambaugh, one of the nurses, were wounded. It is stated that Dr. Dillard's wound is very slight and that he has returned to duty.

Dr. Edward Wallace Lee, Major, M. R. C., U. S. A., has been ordered to report to the Commanding Officer at San Juan, Porto Rico, for active service.

Hospital Annex for Soldiers and Sailors.—At a Loyalty Day celebration at Flower Hospital, on April 21, Dr. Royal S. Copeland announced the gift of a completely furnished 300-bed annex to Flower Hospital to be used for wounded soldiers and sailors from Charles M. Warner. A six-story building immediately adjoining the present hospital building has been acquired for this purpose at a cost of \$100,000 and plans for reconstruction have been completed. The annex will be ready for occupancy by August 1.

Hospitals Forced Back by Falling Shells.—A despatch, under date of April 22, from the British Army Headquarters in France, states that a few nights previously shells began falling on two army field hospitals, killing several orderlies and destroying the operating room of one of the hospitals. These hospitals fell back once only to be bombed a second time and during the retreat the patients were fired upon. The retreat was exceedingly well disciplined and orderly and the patients were moved to safety without the loss of a single one. Nearly all the equipment of these hospitals was saved, several surgeons carrying loads of instruments for distances ranging from twenty-five to thirty miles. It is said that a fine spirit of self-sacrifice and pluck was shown and that the work of the stretcher bearers and their staffs received special commendation.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, April 27, 1918.

A FRENCH VIEW OF SHOCK.

As is well known, the French surgeon has no word for shock and continues to employ the English expression with little effort to assimilate it. For him it appears to be a collective term, applicable to a number of conditions which supervene suddenly, evolve rapidly, and are characterized by marked depression. Shock-like states appear in septicemia, acute anesthetic intoxication, hemorrhage, anaphylaxis, acidosis, cerebral commotion, etc. The war has made necessary a revision of our notions of shock and we can isolate a syndrome to which the term "nervous shock" seems applicable to the exclusion of anaphylaxis, hemorrhage, and other causal factors. In *Le Progrès Médical* for February 9, Roux-Berger and Vignes express themselves in the above language, and emphasize our intense ignorance of the nature of military shock, despite its great frequency and gravity. The numerous and varied hypotheses put forward in recent years as to the mechanism of this phenomenon carry no weight with these authors. It is a significant fact that there is never time or opportunity to study shock clinically, which means that the diagnosis of a given case may have been of the "snap" order. In a subject who has just received a major wound, there are no opportunities to take blood pressures, temperatures, etc. From quite another angle, there is in the phenomenon of shock something so mysterious, so unlike any other form of clinical behavior, that one despairs of ever being able to comprehend its intimate nature.

What is shock from the standpoint of a crude diagnosis? the writers ask. Three symptoms must be present, to wit, depression, lowered animal heat, and lowered blood pressure. Even the symptom depression is something ill defined—we recognize its presence but it is not easily described to others. The depressive state is accompanied by a peculiar inquietude and once seen is always recognizable. Hence diagnosis may be termed a simple matter—that is, simple until we try to associate effects with causes in the search for a rational management. The patient is pale and anxious—he would doubtless also be in a state of agitation were he less depressed. The mere appearance of the patient

suggests a case of severe hemorrhage. There is slight dyspnea which is not present at first. The patient with shock does not cry out and this distinguishes him from a man who is merely badly wounded. The surface feels cold to the hand and if the temperature is taken it will be about 36° C. (96.8° F.). The skin is also a trifle moist. The pulse is miserable and in the worst cases imperceptible. Its rapidity is never less than 140.

Patients recover from shock but it is not because of any surgical treatment they have received, and surgical intervention in traumatic shock must greatly aggravate it. To attempt to give a prognosis in a bad case of shock is extremely unwise. When recovery occurs the symptoms naturally disappear and in the fatal case the temperature and blood pressure show no rallying tendency. The prognosis seems worse in severe lesions of bones. The authors have never seen a severe shock follow a slight wound although others have placed such cases on record. In these cases the real condition may have been fatal syncope which is known at times to follow slight traumas. So-called peritoneal shock is a special clinical type which need not be at all due to accompanying hemorrhage. It is readily intensified by various factors in connection with surgical treatment. In general, implication of the sensory nerve system, especially of the great nerve trunks, has a tendency to augment the severity of the shock. The patient may be in a condition to invite shock, as after exposure to cold and damp, fatigue, vigils, the painful emotions, etc.

But there may be present every element favorable for the development of shock yet no shock may develop; and on the other hand, the patient may not develop shock until he goes under the surgeon's hands. The treatment and prevention of this condition begin with hemostasis. Next in order the patient's animal heat must be conserved by the use of special envelopes and individual heating apparatus. For the pain morphine is necessary and fractures must be immobilized. The patient must be quickly transported to the rear. The field hospital once reached, the warming process is at once intensified by the use of apparatus in which electric lights, hot air, and other resources may be utilized. The heating process may be maintained for as long as 48 hours before the case is deemed hopeless. Progress is indicated by increase in the blood pressure. Circulatory stimulants may be inert. Adrenalin and the injection of a little serum are recommended. There is, however, these authors say, no sovereign remedy for shock; to secure one is the task of the future. First, we must have more and better observation, and then less confusion in nomenclature, before we can treat essential shock.

DILATATION OF THE CYSTIC DUCT AFTER CHOLECYSTECTOMY.

Two articles, relative to gall-bladder and duct surgery, which appeared in the January, 1918, number of *Surgery, Gynecology and Obstetrics*, serve to

emphasize the fact that the way of the surgeon in this region is beset with pitfalls which may easily entrap the unwary. The first article, by Ellsworth Eliot, Jr., deals with the repair and reconstruction of the hepatic and common bile ducts; and he points out that benign strictures of these passages requiring reconstructive surgery ordinarily follow the healing of an ulcer, the result of pressure of a stone or of subcutaneous trauma or, much more commonly, the result of unrecognized division or excision of a segment of the duct in the course of a cholecystectomy or difficult choledochotomy. These injuries to the ducts may be inflicted not only in cases which are rendered unusually difficult because of the excessive adiposity of the patient and the consequent relatively poor exposure of the operative field, or because of the presence of dense adhesions, but also because of occasional anatomical anomalies as to point of division and course of the hepatic and cystic ducts. As Eliot remarks, the identification of the junction of the hepatic and cystic ducts is essential when performing cholecystectomy; and when this is done there should be no danger of injuring the hepatic or common ducts provided reasonable care is exercised when clamping, cutting, and ligating vessels and the stump of the cystic duct.

Yet if, in the anxiety to avoid damaging the other ducts, the section of the cysticus has not been made close to its junction with the hepaticus, the second article referred to above reminds us that besides the Scylla of clamping or cutting too close to and injuring the hepatic or common duct, there is also the Charybdis of leaving too long a stump of the cysticus, which may dilate, form a pseudo-gall-bladder and contain calculi. This was the experience reported by Eisendrath and Dunlavy, who also quote a similar case reported by Floercken and refer to another which occurred in the service of Greensfelder. In the case reported by Eisendrath and Dunlavy a cholecystectomy had been done and the patient had been relieved of all symptoms for a period of two years. At the second operation a dilatation of the cystic duct one inch long and the size of an almond was found. "This pseudo-gall-bladder contained a calculus about the size of a millet seed, and two bean-sized calculi were also found in the common duct which had been overlooked at the first operation." In Floercken's case a cholecystectomy had been done three years previously. At the second operation, which was performed on account of severe colicky pains, the stump of the cystic duct was found dilated to the size of a plum, contained a soft, brown calculus, and communicated with the common duct through a narrow channel.

Eisendrath and Dunlavy, in looking up the literature, found that experimental work done by Oddi, by DeVoegt, and by Haberer and Clairmont showed that when a considerable portion or all of the cystic duct was left after the removal of the gall-bladder in an animal and the animal was killed in from two weeks to six months, this structure di-

lated to form a gall-bladder; but that this did not occur when the cystic duct had been removed close to the common duct. To confirm these findings, Eisendrath and Dunlavy undertook a series of experiments on dogs, using the following technique: "Through an upper right rectus incision, the gall-bladder was carefully separated from its liver bed and ligated with silk at the junction of the cystic duct and gall-bladder. No attempt was made to remove any of the cystic duct. The animals were killed at intervals varying from a week to four weeks, then every two weeks for the second month, and finally every month up to six months." They found that by the end of the first week the cystic duct had dilated so that it was about twice the normal size; that it grows rapidly in size from the second to the sixth week, until by that time a structure is found which greatly resembles a normal gall-bladder in appearance, in that it has a relatively wide fundus and a narrow neck. Their experiments absolutely confirmed the experimental work of Haberer and Clairmont.

Emphasizing the clinical lesson which is to be drawn from these experiments and from the reported cases, Eisendrath and Dunlavy say that Floercken's case, their own, and a similar one in the service of Dr. L. A. Greensfelder of their hospital show that we can have recurrence symptoms through dilatation of the cystic duct to form a new gall-bladder with or without the formation of calculi in the same; and they believe that more care must be exercised in the future to remove the entire cystic duct as close as possible to the common duct.

DESCRIPTIVE HUMAN PHYSIOLOGY.

BEFORE the period of experimental physiology had attained its full flower the textbook writer was wont to fill his space with miscellaneous information on the functions of the human body, much of which was perhaps apocryphal because of the sources from which it was taken. There is, however, at the present time, an increasing need for descriptive textbooks, as shown by the fact that information of this character has now become badly scattered, and is, moreover, no longer monopolized by medical men. All occupations which deal directly with human anatomy and physiology can teach something of value to the latter. The vast number of reflex phenomena used by the neurologist in diagnosis are or depend upon physiological phenomena, yet the student learns nothing of them in his earlier period of training. In descriptive physiology the old idea of a separation of the structure from the functions is of course outlawed; one subject is hardly conceivable in the absence of the other; one fact may be much more static than dynamic, but a distinction between the two types of facts, thus founded, would be eminently artificial.

The subject of the structure and functions of the body is a mine which will still repay working. Let us take a most commonplace and obvious fact, which has probably never been brought home to

the average medical man. He accepts on trust the statement that the normally smooth surfaces of the skin are covered with down. If he wishes to realize this, let him spray some apparently smooth skin with water in an atomizer. If now he examines the skin under a lens he will see many short, fine hairs, upon each of which will hang three or four droplets of water, and which, but for the presence of the droplets, might escape observation. This extremely fine down is of course not to be confused with ordinary lanugo which is readily visible to the unaided eye. The picture is often a most striking one.

In certain individuals a sneezing reflex can be provoked by pinching the nose just below the bony dorsum; in others the same procedure will arrest this reflex. An impending sneeze may often be averted also by pressure on the upper lip at the base of the nose. It is a matter of common experience that a feeling of nausea and malaise can often be banished by a sneeze, whether spontaneous or induced—and this appears to be the simplest and least objectionable method for use; whether or not it has ever been tried in seasickness we are unable to say.

An individual can quickly and surely determine whether he has a bent septum and resulting inequality in capacity of the nasal chambers by a sudden intake of breath, the alæ remaining passive. A vacuum forms in the narrow side and the nostril closes. In this connection we take the opportunity to point out that the expression "a sniff of displeasure" is badly founded. The ladies, we believe, are commonly accused of registering displeasure in this fashion. But a sniff is an intake of breath while the manifestation of displeasure consists of an expiratory effort, which is, moreover, often accompanied by that peculiar grunt of dissatisfaction expressed in type as "humph."

How many men can swallow with the mouth open—or at least wide open? The act is certainly by no means easy of execution, but in all likelihood can soon be mastered by the average individual. The initial difficulty appears to show that in ordinary swallowing we are in the habit of getting a purchase by closing the jaws.

A phenomenon which *a priori* is readily intelligible, but which is little known, has to do with the obliteration of the subclavian artery in many individuals when the chest is fully inflated. A subject who can inflate fully the apices of his lungs may suddenly arrest the radial pulse and a phenomenon of this sort lends itself readily to mystification and simulation.

That a badly frightened man cannot spit, while a "bad" man may show his absence of fear to his kind by spitting freely is well known to a few but should be known to all medical men.

The number of such facts which are at present unutilized in teaching physiology probably runs into the hundreds. Some attempt should be made to assemble and analyze them. A periodical devoted to this quest might be worth the effort. Certainly no man should enter upon the practice of medicine

without a complete equipment of this character, for it would be of infinite service to him in both diagnosis and therapeutics.

AN OBJECT LESSON FOR MAYOR HYLAN.

THE Mayor of this city and his fellow reformers, who are engaged in the effort to disrupt the Health Department, have given evidence of some acumen in proposing first to do away with the least useful because the worst managed of all the several bureaus in the Department. Yet the Mayor is at the same time guilty of ingratitude, for the antagonism of a very considerable portion of the medical profession of the city, especially of Brooklyn, aroused by the dictatorial conduct of the then commissioner, as manifested largely through his publicity bureau, is believed to have contributed quite materially to the overthrow of the former administration. This bureau has been supported on general principle by the Public Health Committee of the New York Academy of Medicine and by various other organizations and individuals, but no one, in the arguments advanced against the dissolution of the bureau, has ventured to commend what the health commissioner has characterized as the press agent methods of the bureau. However, there is no question of the necessity of maintaining the existing organization of the Department of Health, including the Bureau of Public Health Education.

Before the Mayor goes much further in his course of disruption, it might be prudent for him to glance toward Philadelphia and see what has happened there. The Federal Government has taken control of the Police Department of that city because Mayor Smith was unwilling or unable to put an end to vice conditions which threatened the good of the Navy. The government saw the Mayor interfering with war needs and it brushed him aside. The New York Department of Health, through Dr. Park, has already been of great service to the Army in supplying it with needed vaccines and sera. If the Mayor, in his blundering, gets rid of Dr. Park and his corps of experts, the country will suffer, for such a director and such a staff cannot be raised, like Bryan's mythical army, overnight. The government also needs the help of Dr. Josephine Baker's Bureau of Infant Hygiene, and indeed of most of the other bureaus, and it will be likely to interpose a veto if the disloyal work of ruining the Health Department threatens accomplishment. The Mayor would have no face to save if the government should treat him as it has his Philadelphia brother in civic virtue, and he would do well to save it now before it gets beyond repair. Dr. Amster, the present commissioner, also seems to be riding for a fall. When he was appointed his colleagues regarded him as at least a man of good intentions.

A SUBSTITUTE FOR COD-LIVER OIL.

IN spite of the disrepute into which cod-liver oil has fallen in the opinion of many, there is no doubt that it has some value, at least as an easily assimilable nutrient. Those who appreciate this value and

have been accustomed to employ it in their practice have found it to be another drug which the present war has rendered scarce and expensive, so that the news that a satisfactory substitute exists will be welcome information to these. Colonel J. S. Purdy, in a recent issue of the *British Medical Journal*, has called attention to an oil obtained from the mutton-bird, or sooty petrel, a bird which spends nine months of the year in the Antarctic and the balance around New Zealand and Australia. These birds are rich in fat from which an oil is expressed which Purdy has found to be quite as efficacious as *oleum morrhuae*. He had noticed that natives suffering from tuberculosis gained greatly in weight during a native festival called "tangi," at which time large quantities of these oleaginous fowls were consumed. He then experimented with the oil itself with good results. Owing to the fact that it is practically unknown to European and American practitioners as yet, this oil is plentiful and cheap, and it would therefore be well to make the most of this Arcadian state of affairs and eke out the scanty and expensive cod-liver oil with this substitute while it lasts. There should moreover be obtained a powerful psychic effect by the use of "an ingredient procured from a rare bird frequenting the South Pole," and many cures might be effected through the timely use of some such preparation as "Peter Parley's Petrel Pellets."

X-RAYS AND THE WAR.

It is curious but true that even now when it would seem that the x -rays have conclusively demonstrated their value there are medical practitioners who are sceptical as to their use. Some well-known surgeons within recent years have been known to assert that they are able to diagnose injuries or abnormalities better without than with the aid of x -rays. In fact, as is pointed out in an article in the *Medical Press and Circular*, March 13, 1918, there is unfortunately at the present time, although the war has been in progress for nearly four years, widespread prejudice in certain quarters against this branch of medicine. The reason, or the main reason, for this state of affairs is not far to seek. It is chiefly because there is a lack of trained radiologists. It is by no means an easy matter to take accurate and clear skiagraphs nor is it open to the untrained man to interpret them properly. The writer of the article referred to says that the surgeon is fortunate who can rely on the report of the radiologist who knows to a nicety the depth and position of the buried shell fragment, who can decide from which angle he may enter without a haunting fear, born of unhappy experience, that the glib description bears no relation to reality, that the dangerous object lies on the other aspect of the bone, that prolonged search will be unavailing and operation must be postponed until further radiological calculations have been made. It is not then that the x -rays are not of almost incalculable value for diagnostic purposes but rather it is that a dearth of skilled radiologists causes radiology to be held in slight esteem by many surgeons. An untrained radiologist is worse than none at all, for the surgeon will thus be leaning upon a broken reed.

News of the Week.

Children Are Being Deprived of Milk.—A recent bulletin issued by the Children's Bureau of the United States Department of Labor publishes the results of an investigation of 756 Baltimore children between two and seven years of age. It was found that only 29 per cent. of these children were now having fresh milk to drink as against 60 per cent. a year ago. Less than 3 per cent. of the children studied were having as much as three cups of milk a day. With the babies under two years of age the situation was found to be a little less serious. Their needs are apparently a little better understood than those of the child over two years of age. Of the 575 children who were not drinking milk, 64 per cent. had definitely substituted tea or coffee. The foreign-born mothers, though their incomes are slightly lower than the incomes of native born white mothers have more generally than any other group continued to buy milk. The Children's Bureau states that the work of Children's Year should emphasize in every community the importance of fresh milk in the diet of young children and that a campaign of education on the feeding of children is an essential part of the saving of 100,000 lives during the coming year.

Memoir of Dr. John Shaw Billings.—The New York Public Library has available for distribution copies of the Memoir of the late Dr. John Shaw Billings, librarian of the Surgeon General's Office, and first director of the New York Public Library, written by Dr. Fielding H. Garrison, and published by Messrs. G. P. Putnam's Sons in 1915. Medical libraries or librarians who wish the book may secure a copy by forwarding postage to H. M. Lyndenberg, New York Public Library, New York City.

Renew Fight Against Tuberculosis.—The Tuberculosis Committee of the State Charities Aid Association of New York announces the details of a movement to aid local health authorities to deal with tuberculosis growing out of war conditions. Two physicians have been placed at the disposal of authorities throughout the State to aid in establishing dispensaries and providing medical oversight and sanitary supervision. These physicians are Dr. Elliott Washburn, former superintendent of the State Tuberculosis Sanatorium at Rutland, Mass., and Dr. Charles S. Prest of the New York State Department of Health. It is estimated that the draft has revealed 22,000 cases of tuberculosis, the great majority of which must remain at home and hence there is need of a renewed interest in the medical oversight, instruction and assistance of tuberculosis cases.

Work of Children's Year in New York.—In New York City the Mayor's Committee of Women on National Defense, of which Mrs. William Randolph Hearst is chairman, has been designated by the State Council of National Defense as the official organization to carry on the work inaugurated by the Children's Bureau of the Department of Agriculture. A tentative program has been outlined which has as its purpose the saving of 4,700 children under five years of age in New York City during the year beginning April 6, 1918. The

plan includes maternity centers where prenatal instruction will be given, maternity insurance, and proper care at childbirth; the provision of such care and instruction as will keep each baby well during the pre-school age. Centers for pre-school age children will be established in dispensaries, schools, baby health stations, settlements, day nurseries, neighborhood associations, and other organizations. The work will be carried out along borough lines and will be apportioned among the borough committees. There will be committees on speakers, meetings, and propaganda; on examination centers; on social agencies and nursing; on medical care, and on volunteer workers.

Doctor Begins Long Journey to Stefanson.—Dr. Burke, a Fort Yukon missionary physician, has started on a 300-mile snow trail to succor Stefanson, who is wintering at Herschel Island and is suffering from typhoid fever. Dr. Burke has taken five dog teams and hopes by using them in relays to reach Herschel Island in ten days.

Course of Study for Mosquito Fighters.—The Brooklyn Institute of Arts and Sciences announces a course of instruction at the Biological Laboratory at Cold Springs Harbor, Long Island, designed to train persons for practical work in the elimination of flies and mosquitos. The course includes surveys and mapping, identification of species, life history of the different species of mosquitos and flies, specifications for treatment and elimination. The course begins on July 3 and continues for six weeks.

Acting Assistant Surgeon (Female).—The United States Civil Service Commission announces an open competitive examination for women only to fill the position of assistant surgeon in the Public Health Service at salaries of \$1,800 to \$2,500 a year. The appointees to certain of these positions will be expected to make physical examinations of female workers and immigrants, conduct sanitary surveys, and perform other duties of routine character. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C. Applications must be filed prior to May 21, 1918.

Positions at Rome State Custodial Asylum.—This institution offers positions for Assistant Physicians, Clinical Assistants, and Medical Internes. All these positions pay salaries including maintenance and offer opportunities for promotions. The facilities offered enable internes to qualify for army and navy medical service. Further information may be obtained by addressing the Rome State Custodial Asylum, Rome, N. Y.

Positions for Physicians in New York.—The Civil Service Commission of New York State announces competitive examinations for the following positions: *Medical Expert on Tuberculosis*, State Department of Health, open to men and women who are experts on the diagnosis and treatment of tuberculosis, salary \$3,200 a year. *Director of Laboratory*, Department of Health Office, Port of New York, Rosebank, S. I., N. Y., salary \$3,500. *Assistant Medical Officer*, Department of the Health Officer of the Port of New York. The

position is open to men only and carries a salary of \$1,500 a year. *Assistant Physician*, regular or homeopathic, for State hospitals and for positions of a similar nature in various state and county institutions. The salary is \$1,200, increasing gradually to \$1,600, with maintenance. Applications must be in the hands of the Commission before May 15. Further information may be obtained by addressing the State Civil Service Commission, Albany, N. Y.

Medical Society Elections.—THE MASSACHUSETTS HOMEOPATHIC MEDICAL SOCIETY at its seventy-eighth annual meeting held in Boston, on April 10, elected the following officers: *President*, Dr. W. H. Waters of Boston; *First Vice-president*, Dr. Elmer H. Copeland of Northampton; *Second Vice-president*, Dr. Wesley T. Lee of Boston; *Recording Secretary*, Dr. Edward S. Calderwood of Roxbury; *Corresponding Secretary*, Benjamin T. Loring of Watertown; *Treasurer*, Dr. Thomas M. Strong of Boston; *Chairman of the Board of Censors*, Dr. Alonzo H. Howard of Boston.

THE TENNESSEE STATE MEDICAL ASSOCIATION, at its meeting in Memphis, Tennessee, on April 10, elected the following officers: *President*, Dr. Richard M'Kinney of Memphis; *First Vice-president*, Dr. W. H. Tucker of Halls; *Second Vice-president*, Dr. Horace Farrar of Hillsboro; *Third Vice-president*, Dr. A. G. Kern of Knoxville; *Secretary* (re-elected), Dr. Olin West of Knoxville; *Trustee*, Dr. C. J. Boyles of Johnson City; *Delegate to the American Medical Association*, Dr. E. T. Newell of Chattanooga.

THE FAIRFIELD COUNTY MEDICAL ASSOCIATION, at a meeting in Bridgeport, Conn., on April 9, elected the following officers for the ensuing year: *President*, Dr. F. I. Nettleton of Shelton; *Vice-president*, Dr. J. R. Hertzberger of Stamford, Conn.; *Secretary*, Dr. C. W. Gardner of Bridgeport; *Treasurer*, Dr. H. B. Lambert of Bridgeport; *Acting Treasurer*, Dr. F. W. Stevens of Bridgeport; *Councilor*, Dr. F. H. Barnes of Stamford.

THE TRI-STATE MEDICAL, DENTAL, AND PHARMACEUTICAL ASSOCIATION, at its meeting in Memphis, on April 11, elected the following officers for the ensuing year: *President*, Dr. J. H. Barabla of Marianna, Ark.; *First Vice-president*, Dr. M. V. Vembla of Oakland, Tenn.; *Second Vice-president*, Dr. J. T. Brasfield of Memphis; *Third Vice-president*, Dr. Isaac Carroll; *Fourth Vice-president*, Dr. F. T. Jones; *Fifth Vice-president*, Dr. W. T. Sherred; *Recording Secretary*, Dr. R. P. Pruitt; *Corresponding Secretary*, Dr. R. G. Martin; *Treasurer*, Dr. S. W. Pope.

Dr. S. S. Goldwater has tendered his resignation as chairman of the Mayor's Committee on Hospital and Medical Facilities. Dr. Goldwater will, however, at the request of the Mayor, continue to serve as a member of this committee.

Dr. James Peter Warbasse of Brooklyn, N. Y., has been removed from membership in the Medical Society of the County of Kings. He was accused of opposing military training and of defaming the medical profession. It was voted to submit a report of the proceedings to the Department of Justice.

Leper Colony Buys Thrift Stamps.—The National War Savings Committee announces that the

lepers at Molokai have bought \$3,000 worth of thrift and war-saving stamps as their contribution toward the cost of winning the war. The leper camp flies the Stars and Stripes and is furnishing an example of patriotism from an unexpected source.

The Medical Library Association.—Owing to present conditions and the difficulties of travel, the Executive Committee of the Medical Library Association has decided to omit the regular meeting this year.

The Late Dr. Guiteras.—The Harvard Medical Society recently adopted the following resolution: *Whereas*, the death of Dr. Ramon Guiteras, a charter member of the Harvard Medical Society of New York City, has recently occurred following a brief illness, thus taking from the Society one of its most beloved and distinguished members: *Be it resolved*, that the Society record its sincere grief and regret for the loss of one whose personal charm and lovable quality, associated with eminent professional attainments, made a combination the worth of which is universally acknowledged. *Be it further resolved*, that the Secretary send a copy of these minutes to Dr. Guiteras' sister, together with the Society's deepest sympathy. *Signed*: Eugene Fuller, M.D.; E. M. Foote, M.D.; Charles R. L. Putnam, M.D., Committee on Resolutions.

Obituary Notes.—Dr. FREDERICK VEAZIE HARDWICK died of pneumonia at his home in Dorchester, Mass., on April 9, aged 40 years. He was a graduate of Harvard Medical School, in 1904. In his district Dr. Hardwick was chairman of the Local Board, secretary, and medical examiner, and is credited with the plan to provide all Boston boys called to the colors with comfort kits and boxes. It is believed that his unremitting labor in connection with this work is largely responsible for his death.

Dr. SARAH J. WHITE, a graduate of the Women's Medical College and Hospital, New York, in 1873, died suddenly at her home in Unionville, Conn., on March 19, aged 78 years.

Dr. GEORGE HOSLEY SHEDD, a graduate of Bowdoin Medical College, in 1879, died suddenly at his home in North Conway, N. H., on March 21, aged 65 years.

Dr. IRVING ALLISON WATSON, secretary of the New Hampshire Board of Health, died at his home in Concord, N. H., on April 3, aged 69 years. He was a graduate of Dartmouth Medical College, in 1871.

Dr. COLUMBUS E. MCCOY, of Bozeman, Mont., a graduate of Vanderbilt University Medical Department, Nashville, Tenn., in 1895, died after a brief illness, on March 21, aged 47 years.

Dr. ROLANDUS G. WALKER, a graduate of the Cleveland College of Physicians and Surgeons, in 1904, died of pneumonia at his home in Denver, Col., on March 21, aged 51 years. He was formerly a resident of Canton, Ohio.

Dr. ALFRED H. TANNER, a graduate of Bellevue Hospital Medical College, in 1874, died suddenly at his home in Brooklyn, Conn., on March 22, aged 66 years. Dr. Tanner was for many years medical examiner of the town of Brooklyn.

Dr. THERON T. HUBBARD, a retired physician, formerly of Saginaw, Mich., died at the Soldiers' Home

at Grand Rapids, on March 21, aged 84 years. He served as a surgeon in the army during the Civil War.

Dr. CHARLES B. KENNEY, a retired physician of Portland, Me., and a Civil War veteran, died suddenly on March 25, aged 69 years.

Dr. JOSEPH PAINTER CREVELING, a graduate of the University of Michigan, in 1870, died suddenly of apoplexy, at his home in Auburn, N. Y., on March 30, aged 70 years.

Dr. CHARLES R. WHITCOMBE, a graduate of the Long Island College Hospital in 1883, died at his home in Roslindale, Mass., on March 9, aged 64 years.

Dr. NATHANIEL G. BROOKS died at his home in Charleston, N. H., on March 17, aged 80 years. He was a graduate of the Albany Medical College, in 1861, a surgeon in the Civil War, for some years in charge of the hospital at Brattleboro, and later a representative to the legislature and a State senator.

Dr. WILLIAM ROBERTS SIMPSON, a graduate of Washington University Medical Department, St. Louis, in 1871, died at his home in Chillicothe, Mo., March 13, aged 72 years.

Dr. EDWARD L. SALMON, a graduate of Harvard Medical School in 1905, died of pneumonia at his home in Southboro, Mass., on March 17, aged 41 years.

Dr. LAWRENCE B. HATHAWAY, a graduate of Rush Medical College in 1878, died at his home in Rheinebeck, Iowa, after a long illness, on March 17, aged 64 years.

Dr. IRVING ALLISON WATSON, secretary and executive officer of the New Hampshire Board of Health since its organization in 1881, died at his home in Concord, N. H., on April 3, after an illness of several weeks, at the age of 69 years. He was a graduate of the University of Vermont Medical College in 1871. Dr. Watson served at one time in the New Hampshire House of Representatives, was secretary of the New Hampshire Commission of Lunacy, registrar of vital statistics of New Hampshire, and president of the State Board of Cattle Commissioners. He was a former president of the New Hampshire Medical Society and assistant general secretary of the first Pan-American Medical Congress.

Dr. CYRUS B. KING, a graduate of Jefferson Medical College, in 1867, died at his home in Pittsburgh on April 9.

Dr. WILLIAM F. M. MCALLISTER of San Francisco, Cal., a graduate of the University of Pennsylvania, in 1870, died on March 29, aged 77 years. Dr. McAllister, at the age of seventeen, took part in the John Brown raid at Harper's Ferry, in 1859, being the last surviving member of that expedition. He was a Civil War veteran, with the rank of major.

Dr. GEORGE GOLDING KENNEDY, a graduate of Harvard Medical School, in 1867, died at his home in Milton, Mass., on April 1, aged 78 years.

Dr. ASA F. GOODRICH, a graduate of the Hahemann Medical College and Hospital, Pennsylvania, in 1889, died of pneumonia at his home in St. Paul, Minn., on March 29, aged 53 years.

Dr. FRANK M. GIER died at his home in Hillsdale, Mich., on March 28, aged 59 years. He was a graduate of the University of Michigan, in 1884, and had served as president and secretary of the Tri-State

Medical Society and as surgeon-general of the Sons of Veterans of the United States. He was chairman for Hillsdale County of the Military Training Camps Association.

Dr. JOHN A. BOSWORTH, a graduate of the Boston University Medical College, in 1879, died, after a long illness, at his home in Roslindale, Mass., on April 5, aged 64 years.

Dr. EDWARD PAYSON HAMILTON GRISWOLD, a graduate of New York University Medical College, in 1878, died at his home in Niagara Falls, N. Y., on April 1, aged 63 years.

Dr. AUGUSTUS CHAPMAN WALKER, a retired physician of Cambridge, Mass., died at his home on April 4, aged 85 years. He was a graduate of the Harvard Medical School in 1866, served as a surgeon in the Civil War, and later served as a United States pension examiner and a member of the Massachusetts Board of Registration in Medicine.

Dr. MARCUS MILTON CATLIN, a graduate of the Cleveland Homeopathic Medical College in 1868, and a Civil War veteran, died of pneumonia at his home in Canton, Ohio, on April 4, aged 71 years.

Dr. ELISHA J. THURMAN, a graduate of the Washington University Medical Department, St. Louis, Mo., in 1873, died at his home in St. Louis, Mo., on March 31, aged 78 years. He served as a surgeon in the Confederate Army during the Civil War.

Dr. WILLIAM J. HILLS of Chelmsford, Mass., a graduate of the Harvard Medical School and a Civil War veteran, died in Florida, following a prolonged illness, on March 30, aged 77 years.

Dr. WILLIAM WINFIELD NELSON, a graduate of the University College of Medicine, Richmond, Va., in 1901, and a practitioner of medicine in that city, died after a long illness, on April 8, aged 38 years.

OUR LONDON LETTER.

(From Our Own Correspondent.)

NATIONAL SERVICE AND MEDICAL STUDENTS—THE NEW PRESIDENT OF THE COLLEGE OF PHYSICIANS—SMALLPOX IN LONDON—PREVALENCE OF VENEREAL DISEASE—NEW MEDICAL OFFICERS FOR THE ARMY—DEATH OF DR. SALUSBURY TREVOR.

LONDON, March 28, 1918.

THE question of the employment of medical students in a combatant capacity in the army was one concerning which much difference of opinion prevailed at the outset of the war. In medical and scientific circles those who thought most about the matter were perfectly clear that to use medical students as soldiers or sailors because of their fighting value was to lose sight entirely of their enormous potential value as medical practitioners. The scientific view was overruled entirely, the main factor in this situation being the students themselves, who, while their teachers were discussing how exemption could be extended to them, betook themselves with promptitude to the recruiting sergeant or obtained commissions in various branches of the forces. When the possible effect of a complete denudation of the medical schools was realized, and the certainty of a shortage of medical practitioners in the years to come had been incurred, senior students, that is to say, those between whom

and qualification only their final tests remained, were allowed to return to their studies, although of these students the navy made adroit use by turning them into "surgeon probationers," and employing them as dressers and clinical assistants at the naval bases and hospitals, and in some cases on board ship. The idea of letting back to their studies senior students only was two-fold in origin: first, these were the men who would most quickly fill the gaps in the medical register by taking their diplomas; and, secondly, they were medical students of whose status as such there could be no doubt. This was not so with a medical student who had just joined a school or had only passed his first professional test. The military authorities saw in the exemption of such students the opening up of a clear way of avoiding a national duty, for any boy who from personal motives or parental influence desired to escape could join a medical school. As, however, the war has gone on, and as the possible shortage of medical men has come more home to the community, a valuable revision of opinion has taken place in military circles. The latest official declaration (National Service Instruction V. 1918) provides that a medical student who has passed his first professional examination in chemistry, physics, and biology, will not be called up for combatant service so long as he joins a training corps and can prove in the usual way that he is diligent in working for the next examination in anatomy and physiology. The Instruction applies to students also who have not passed the first professional examination, but who do so before the end of next July, by which additional concession medical study practically becomes "a reserved occupation," the technical phrase for civilian occupations exempt from conscription. Even now the military authorities have not gone far enough to be quite fair, because the first-year medical student who enlisted on or soon after the outbreak of the war does not appear to be under consideration. The number of these students left in the army now may be small, and many of them possibly have no desire to resume the medical career so abruptly cut short three and a half years ago, but it would have been wise of the authorities to have given them the opportunity and thus prevented a legitimate source of grievance.

The election of Dr. Norman Moore to the presidency of the Royal College of Physicians of London makes one of the most learned of our physicians titular head of the medical profession—a position on which that august mediæval body, the College of Heralds, was consulted, when, as president of the General Council of Medical Education and Registration Sir Richard Quain claimed, and certainly with a good show of logic, the precedence. Dr. Norman Moore, who took a high degree in classics at Cambridge and was elected a Fellow of St. Catharine's College, is consulting physician to St. Bartholomew's Hospital and has rightly attained to his presidential post by unceasing and devoted work for the Royal corporation. A frequent office-bearer and constant attendant at *comitia*, he has used a pretty talent for pungent speaking to maintain the conduct of college affairs along dignified paths, while as representative of that body on the General Medical Council he proved by argument,

and further by his personality, that the corporation, though old in date and conservative by tradition and constitution, could play a valuable part alike in the reform of medical education and in the maintenance of high professional standards. Dr. Moore, "a man who reads books and not books about books," has brought his historical and classical learning to bear upon numerous sections of medical history, while he has been the candid biographer of many of the members of the medical profession whose record has entitled them to a place in the Dictionary of National Biography.

At the end of February five cases of smallpox came under treatment in one of the hospitals of the Metropolitan Asylums Board, and during March some ten other cases occurred, all in the eastern quarter of the city. Vigorous inspection, notification, and vaccination of contacts have suppressed the disease.

The prevalence of venereal disease, and especially of gonorrhea, among the armies both at home and abroad, though no longer the source of real apprehension that it was two years ago, is none the less a drain upon man-power of a sort that ought to be prevented. At home the work of the National Council for the Prevention of Venereal Diseases has done real good, despite the division of opinion upon the real scope of the council, while the foundation of venereal clinics has provided centers at which sufferers can obtain prompt care. Medical men, attending at the center and observing the clinical practice of experts have thus learned to deal with cases by the modern effective methods as they occur in practice. None the less, those who know most of the incidence upon the population of venereal disease, dread a big spread of the plague when the armies are disbanded, judging by the numbers of the cases already known to exist. Chronic gonorrhea is the chief source of the evil, the woman being often unaware that she is infectious, and the man only aware of it when a particular occasion of sexual indulgence produces what he believes to be a new attack, but what is, of course, only an exacerbation of a chronic condition. An infection of the prostate gland and seminal vesicles turns such men into potent "carriers," and they are now being especially watched for at many venereal centers, where they are induced to undergo proper treatment.

The events of the last week in March made it clear that from among the civilian medical profession a number of new medical officers would have to be immediately supplied to the army, for it was inevitable that the German advance should mean a loss of a certain amount of medical personnel as well as material and stores. It would not be permitted to state in print the actual number of medical men, regular and temporary officers of the R. A. M. C., who are at present abroad, although, as the sum total of our armies has been mentioned in Parliament on several occasions, and as the ratio of doctors to men has become a fairly constant one, the figure can easily be guessed. But at least twice that number of doctors have also been swept into the service of the navy and army combined, leaving the civilian population in some places distinctly bare of medical protection. The particular place where this requires most watch-

ing is in panel practice, for the departments of State, like the Local Government Board and the Board of Education, have been able to maintain the right of exemption for sanitary and educational medical officers. The National Insurance Commission has not been so fortunate for their medical service, and in some places panel practice has distinctly suffered. The number of persons who have a right under the National Insurance Act to treatment on panels is difficult to ascertain in the present conditions of flux, but probably the rough figures are something like this: The total population of the United Kingdom is a little over 45 millions, from which $4\frac{1}{4}$ millions can be deducted for Ireland, which is not under the scope of the National Insurance Act and, incidentally, of the conscription regulations. The 40 millions, and a little more, of England, Scotland, and Wales include almost exactly one-half in that number of persons under 15 years of age, to whom for that reason the Act does not apply. Of the remainder, a rough estimate is that 10 million men and 4 million women look to the panels for their medical care. The Central Medical War Committee, in whose hands exemption rests, is fully aware that the source from which new medical officers has to be drawn represents also the medical service for these 14 million people comprising over one-third of the population of England, Wales, and Scotland. The consequence is that further drafts on the general practitioners of these countries for military service are beginning to be viewed with apprehension and satisfied with difficulty.

Dr. Salusbury Trevor, whose suicide during temporary insanity occurred last week, was not only one of the best practical authorities in the country on forensic medicine, but a well known student of Anglo-Saxon literature, and a beautiful singer. He was Dean of St. George's Hospital, and his loss is a sad one to that institution, as well as to a wide circle of friends and to medical science.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

AMERICAN AMBULANCES IN ITALY—WORK OF THE RED CROSS IN BELGIUM AND FRANCE—A MILITANT Y. M. C. A.

PARIS, March 18, 1918.

WHEN finally the British and French authorities decided to send troops to aid Italy to stem the tide of the onflowing hordes that threatened to overrun her State, the question of supplying a medical corps to accompany these armies was found to be a very difficult one; existing conditions did not permit of withdrawing surgeons from the northern front and practically a new corps had to be formed from the hospitals of the larger centers. In view of these difficulties the offer of certain sections of the splendid Harjes-Norton Ambulance Corps, that was broken up when the American Army attempted its absorption, to go to that front were gladly accepted and the fourth section of this American Arm of the service has just left Turin for the front. Its departure gave occasion to a great and enthusiastic demonstration for the United States. Flowers were piled on the ambulances by the crowd, while bands played Ameri-

can airs and soldiers rendered military honors. The section comprised twenty-five ambulances and its departure was witnessed by Major Woffmer of the American Red Cross.

Dr. J. H. Mason Knox has been appointed medical director to the Belgian Commission of the American Red Cross. He will continue as associate chief of the Children's Bureau, acting as medical representative of the Commission for Belgium, and as liaison between the Paris and Havre services.

Seven buildings in Paris have just been brought to completion through the Red Cross Bureau of Refugees and Relief, and are now housing more than two hundred refugee families. Twenty-six buildings in Paris are now in the course of completion, these buildings to accommodate over 700 families, and since most of them are "familles nombreuses" this means about 3,850 individuals.

The Red Cross has ordered ten portable bath plants for American Army camps. Some of these are already under construction. They will have varying capacities, some having accommodations for 1,000 men a day.

The ordinary citizen unacquainted with the details of the work of the Y. M. C. A. in America is imbued with the idea that it is a sort of goody-goody affair, made up of milk sops, where ma, at home, sends her boy from the country when he comes to the city so that he may be safeguarded from the temptations and evils that lie in wait for him on every hand. Anyone coming to know the work undertaken by the organization in France would be compelled to revise his opinion of its character and activities.

In the cellar of a house that is considerably damaged by shell fire and which is under fire every time the Germans take a notion to shoot that way, a Y. M. C. A. center is being operated out from Toul for the American soldiers who are now holding the line. The village, of which this house is a part, is a mass of ruins, scarcely an entire wall standing anywhere. The Red Triangle sign is over the cellar door and when one enters he will find there soldiers wearing their "Carnegie derbies" and with gas masks handy. Just a small amount of floor space is available, but on this there is a canteen and over in a corner a small gramophone is often in use.

In another village not far distant the Y. M. C. A. is found by going up the partly demolished stairway of a partly demolished house which stands in an almost wholly demolished village. Crowded into a medium-sized room are a canteen, some chairs, and a place or two for writing. This village, too, is under fire whenever the Prussians choose to shoot at it. The line is just a little way distant. American artillery around these villages is making life uncomfortable for the Germans.

In still another shell-shattered village, which also is close up, the Y. M. C. A. is reached by climbing up a ladder. In another village the Red Triangle sign is on a building which the French formerly used and called a "salle de réunion." And shells can find their way into that section also.

And so on the story goes. The Y. M. C. A. has gone forward with the troops. It is offering such

edibles as can be had, and such little comforts as are possible. Every evening or two the Y. M. C. A. trucks go forward along the roads, carrying supplies to these advanced huts. It is much more healthy to travel on some of these roads after dark than in daylight. The trucks carry up chocolate, when it is to be had; packages of fruits, tobacco, and magazines.

Arrangements have now been made to serve to the men hot drinks free of charge. The arrangement is to have something hot for the men when they return from the trenches, which are just a little distance from these advanced "huts." Hot drinks seem to be what these men want, so the Red Triangle will try to supply the want.

A trip "up the line" reveals a chain of just such Red Triangle centers, some of which are double-walled tents, some rooms in battered houses, and some in cellars. Just whatever is available can be made to suffice. There is not so much time for the ordinary Y. M. C. A. activities in "those parts," for the magnificent body of fighters which is there is bent upon fulfilling its stern mission.

Before the advance of the troops to the trenches the Y. M. C. A. made its preparations to go with them. Automobile transports were provided and held in readiness. Supplies were secured in such quantities as possible and were sent ahead. Many a soldier coming to these refugees wet through and almost frozen finds here the warmth, comforts, and attention that save him from a possible pneumonia and fit him anew for his tasks.

2. Hemorrhage from the Uterus in the Non-pregnant Woman.—Frank A. Pemberton enumerates the various causes of menorrhagia and metrorrhagia. He states that when bleeding occurs in the acute infectious diseases a pelvic cause should always be searched for. Sarcoma of the cervix should be considered in all cases of bleeding before puberty. Excessive bleeding in the first decade after puberty is probably due to an excessive production of the internal secretion of the ovary—or uterine insufficiency. Pemberton draws particular attention to the more troublesome conditions: chorio-epithelioma, in which the first warning is a sudden hemorrhage following the passing of a hydatid mole, a miscarriage or labor. A bluish tumor in the cervix or vagina is a diagnostic sign. In positive cases the tissue shows syncytium and Langhan's cells, or either one of these alone. The small submucous fibroids present difficulty in diagnosis and require ether examination; such fibroids should be excised, as from one to two per cent. of these undergo sarcomatous degeneration. Uterine polypi can be diagnosed only with the curette, and this is true also of polypoid gland hypertrophy. Carcinoma of the cervix is the principal cause of bleeding after the menopause and with its preceding stage, erosion of the cervix, comprises 54 per cent. of all cases. Carcinoma of the uterus comprises a further 12½ per cent. Bleeding in a woman over seventy years of age

means cancer of the fundus of the uterus. The three types of cancer must be borne in mind—epithelioma of the outside of the cervix, adeno-carcinoma of the cervical canal, and adenocarcinoma of the fundus. In the early stages these can be diagnosed by the microscope. When well advanced the epithelioma can be recognized by its ulcerated appearance, if the tumor is of the corroding type, or by the cauliflower appearance, if of the so-called everted type. In adenocarcinoma of the cervical canal when first seen, the external os has usually ulcerated away. Should the cervix appear normal, however, the canal should be scraped with a small curette and the tissue examined by a competent pathologist. A large amount of crumbly soft tissue with sharp bleeding is cancer. Adenocarcinoma of the fundus usually occurs after the menopause. In making an examination for cancer it must be remembered that polyps and fibroids may occur together; and that fibroids and cancer may also be found together; and that senile vaginitis may mask an early cancer. A D & C should be performed in all cases where the cause of the trouble is not immediately obvious, except in the case of a young girl with menorrhagia just commencing. The treatment indicated, especially in the case of girls and young women, is rest in bed when the bleeding is profuse. Should this fail to bring about improvement, an ether examination should be made. Packing of the vagina may be resorted to. Drugs are of little benefit, although pituitrin may be of value in young women. Dilation and curettage finds its greatest value in diagnosis. Abdominal operation should be done in cases of malignancy. The most satisfactory treatment, however, is by radium and the x-ray. They both have the effect of killing the follicles in the ovaries and thereby lessening the internal secretion. Radium is the more powerful in its effects; moreover, if the x-ray were continued for long, burns of the skin would result. The latter is the more expensive on account of the apparatus required. In the case of the young girl with uterine insufficiency Pemberton places 50 mg. of radium in the uterus and leaves it from four to twelve hours. The x-ray is more effective in women of over forty years of age; it rarely causes a permanent amenorrhea in young women unless the treatment is continued. Both are valuable means of decreasing bleeding in fibroids. Radium is especially valuable in stopping bleeding from inoperable cancer of the cervix; care must be taken, however, in its employment, as if too strong a dose is used vesico-vaginal and recto-vaginal fistulae may result.

2. The Treatment of Cancer of the Lip by Radium: A Report of Twenty-four Cases.—Henry H. Janeway refers to the greater curability of lip cancer over other forms. The cancer usually occurs in the lower lip and more frequently in men than in women, the etiologic factor usually being tobacco. He gives the results of radium therapy in two series of cases. In the first of six patients with early cancer of lip, treated in 1915-16 at the Memorial Hospital, New York, five were traced to January 1, 1918, and in one only had there been a recurrence; in the case not traced, the lesion had entirely disappeared when last seen. A second series of eighteen cases was treated during the past year with satisfactory results. The average duration of the lesion before treat-

ment in the two series of cases was thirty months, the time varying from one month to twelve years. Janeway points out that the critical factor is the rate at which the lesion is growing at the time of treatment. He found that in treating cases by radium the best results followed single treatments. With exception of three cases, all of which had advanced lesions when they applied for treatment, all the patients in the series are now free from evidences of disease. Though the true value of these results cannot yet be determined, Janeway considers that they justify the use of radium in operable cancer of the lip. The method of treatment includes, however, the careful observation of patients after treatment for the possible development of metastatic lymph nodes, and the operative removal of such when they occur, with the implantation of radium in the wound. He believes that the treatment of cancer of the lip by radium will encourage earlier attention to this disease by the patient. He recommends the application of radium emanation embedded in molds of the dental compound, and filtered through the thinnest material for the most superficial lesions. He has used 0.5 mm. of silver uniformly for all but the lesions with deep infiltration with satisfactory results. For the deeper lesions he has found that nothing surpassed the progressive, smooth and complete retrogression produced by filtration through 1 mm. of platinum. The tubes should be sunk 5 mm. in the dental compound and for the ordinary lesion the dose should be 60 millicurie hours per square centimeter, when the filtration is through 0.5 mm. of silver and 100 mc. h. per square centimeter when through 1 mm. of platinum. The use of emanation instead of radium element facilitates uniform distribution, which is an important factor. In the majority of cases of cancer, treatment by radium element is inefficient.

8. Two Uncommon Forms of Intussusception Occurring Simultaneously in the Same Patient. John A. C. Macewen.
4. Radium Treatment of Scars: With Clinical Notes on Military Orthopedic Cases.—Captain Walter C. Stevenson has treated a number of cases of scar tissue and fibrous adhesions—some of which had previously been given massage and other treatment for months—by radium emanations. The radium was supplied by the Royal Dublin Society Radium Institute and the dosage employed per area treated for a thin part like the hand was about 320 millicurie hours, and for a more fleshy part 360 mc.h. For instance, utilizing an average of 40 mc., the time the applicator would be left on the hand is obtained by dividing 320 by 40—i.e. eight hours, and similarly for the arm nine hours. The results obtained have led Stevenson to draw the following conclusions: (1) Radium has a distinct sphere of usefulness in the treatment of scar tissue and fibrous adhesions; (2) It is a valuable adjunct to other methods of orthopedic treatment, especially by shortening their duration; (3) Its effect is rapid, sometimes immediate; (4) It softens and mobilizes scar tissue; (5) It appears to facilitate subsequent removal of the scar by the knife; (6) It enables structures, like tendons, adherent to the scar, to free themselves; (7) By loosening tendons and stiff joints it improves the functional power of the part; (8) It possesses the advantage of acting, to some extent, as an innocuous local anesthetic for about a week; (9) It is particularly useful in treating scars and adhesions in the hands and fingers; (10) It is easily applied to the

surface of the skin, and by this method causes no inconvenience to the patient; (11) To obtain the best results a single large dose is necessary; (12) The dose should not be so great as to produce inflammation of the skin; (13) With suitable dosage it appears to produce no ill effects; (14) In small doses it appears to hasten the healing of wounds, and to allow the painful inhibitory effects of the products of inflammation.

5. Post-operative Thrombosis and Embolism. Charters J. Symonds.

4. The Treatment of Infected War Wounds by Magnesium Sulphate.—Albert E. Morison points out that in the Field Ambulance or the Casualty Clearing Station all that may be possible in the treatment of war wounds is the application of some dressing which will protect the wound and diminish the chances of infection. Magnesium sulphate cream would seem to provide such a dressing. Morison has employed this preparation in about one hundred cases under conditions which resemble as closely as possible those at the front, and has obtained satisfactory results. The procedure adopted was as follows: The dressings with which the patients arrived in hospital, most of which were applied from two to five days previously, were removed. A culture was taken of the organisms—aerobic and anaerobic—present in smears from the wound, and without any preliminary cleansing of the wound itself or of surrounding parts; magnesium sulphate cream was then applied to the wound under a suitable dressing. The dressing was left untouched for from three to five days. Bacteriological and clinical examination was then made of the discharges and the wound. The cream is prepared in the following manner: 1.5 pound of manges. sulph. exsiccatum are mixed with 11 ounces of glycerin acidi carbolici (1 to 10). The dried magnesium sulphate is in the form of a fine white powder, which contains 12 per cent. less water than the ordinary. The glycerin acidi carbolici is put in a hot mortar and the sulphate added, slowly stirring and mixing with a warm pestle all the time. The result is a thick, white cream, so hygroscopic that if exposed to the air it rapidly absorbs moisture and becomes fluid, which must be preserved in a covered jar. The addition of the carboic acid was made because of its analgesic properties, but it was found to be unnecessary, as the application of the cream, even without the carboic acid, causes no discomfort, beyond a slight feeling of coldness. The wound is packed and thickly covered with the cream, and the dressing of gauze and cotton wool is left unchanged for from three to eight days. A profuse discharge of serum takes place, so that more wool may have to be applied over and around the original dressing. On removing dressings any discharge there may be is seropurulent and escapes easily, and the wound surface is covered with bright red granulations, filmed over by a thin layer of grayish lymph containing a few pus cells. A similar dressing is again applied, spread thickly on gauze. In the case of the deeper wounds, such as fractures, the cream is syringed into the deepest part of the wound by passing a piece of drainage tube attached to the syringe into it, and filling the wound with cream. More cream spread on gauze is applied to the surface. After a few dressings in this manner the dressing is changed to magnesium sulphate solution, and the edges of the wound brought together with sutures or skin grafts applied under local anesthesia. In deeper wounds when a fracture is present loose pieces of bone should be removed under anesthesia, the wound washed out with ether or petrol, then dried with gauze mops and smeared thoroughly with bipp or X. Y. Z. paste. The guides to closure of the wound are bacteriological findings of the discharge and the amount and clinical

nature of it. Morison concludes that magnesium sulphate cream presents the following advantages: (1) Simplicity of application and the rapidity with which large numbers of cases can be dealt with—as in field ambulances and casualty clearing stations. (2) The infrequency of dressings, which even in the most septic cases need no change from three to eight days. (3) The combined osmotic action and the inhibitory effect on the growth and development of such ordinary organisms as are usually found in wounds—aerobic and anaerobic—together with its nontoxic action on the patient, make this a valuable dressing in the first stage of wound treatment, where the aim is to get rid of sphacelated tissue and minimize sepsis. (4) Its sphere of action as a rule ceases after the first stage, because epithelialization is inhibited and granulation tissue formation delayed as soon as the wound has been cleansed. (5) In the second stage of wound healing, that is, the encouragement of repair, other remedies should be employed, though it is useful with chronic sinuses or wounds which require stimulating.

5. Postoperative Thrombosis and Embolism.—Charters J. Symonds points out that pulmonary embolism does not occur after operation above the diaphragm; nor does it occur in children. He suggests that an explanation of this may be found in the fact that free movement is permitted in operations above the diaphragm and cannot be avoided in children, as it is impossible to prevent them from moving. Symonds suggests that the restriction of movement after abdominal operation, and also after parturition, the enforcement of the dorsal position, and the use of knee pillow, may be the determining factors in massive thrombosis through retardation of the circulation and that such restrictions should be abandoned, together with the use of the knee pillow, and that daily movement should be insisted upon. He states that the observation that vigorous vomiting even for a couple of days appeared to have no injurious effects in cases of abdominal operation led him to abandon the rigid recumbent position.

On Some Problems of Tuberculosis.—J. Orth offers some benign considerations on the evolution of our knowledge of tuberculosis and on its terminology. Passing to the question of traumatic tuberculosis, Orth appears inclined to attribute such processes to an endogenous infection resulting from the awakening of a latent focus. This is an old story so far, but at this point the writer does not join in the generally accepted notion that tuberculosis in the adult is in most cases a delayed manifestation—one might say a tertiary phase—of an infection arising in childhood. The frequency of tuberculous lesions in the adult, when compared with their frequent absence in children, forces one to admit an exogenous infection in many adults.

The Treatment of Whooping Cough.—Aufrecht is of the opinion that there is little virtue in most of the therapeutic measures now employed for this affection. He recommends the most absolute quiet, even immobility of the child, as this decreases the number of paroxysms of coughing and shortens the length of the morbid process, likewise preventing the advent of complications. A mild infusion of ipecac is exhibited.

The Differences in the Results Obtained from the Wassermann Reaction.—H. Mayer defends this reaction against the attacks made upon it by Freudenberg (the writer is apparently unaware of the almost universal attacks to which the Wassermann has been subjected for the past five years), who brings forward the contradictory results obtained in laboratory work on different samples of the same blood. According to Mayer, Freudenberg's arguments are completely based upon insinuating statistical tables. However, Mayer has admittedly been obliged to search for the cause of these divergences in the results of examination in different laboratories, and he attributes them to technical errors and to the utilization of different antigens (extract of syphilitic liver, or extract of guinea pig's heart, etc.). The reform claimed for by Freudenberg should, therefore, not be applied to the method of the reaction, but rather more to the procedures employed, as well as a

more careful and exact execution of the teachings of Wassermann and his school.

The Treatment of Malaria.—L. R. Müller is of the opinion that the systematic use of quinine as a prophylactic has not given the results hoped for, and it can even be upheld that its effects in reality render the plasmodium resistant to quinine. A most important prophylactic measure consists in the detection of latent carriers of the parasite, who by the intermediary of mosquitos may very well spread the disease. Detection can be made by blood examination and by provoking paroxysms of the disease by injecting thermogenous substances, sterilized milk, or irradiation of the spleen with a quartz lamp. The latter represents a great progress in malarialogy. Müller is quite positive that malarial antibodies are present in the blood of subjects belonging to infected regions, as well as in the blood of patients in full evolution of the disease. These antibodies are very labile and do not exist longer than the pathogenic agent itself. Müller prefers quinine hydrochlorate and has found that treatment with salvarsan alone gives poor results, and should, therefore, always be combined with quinine or methylene blue. To conclude, Müller has not found that Ehrlich's so-called specific has proven itself of any great value in malaria.

Chronic Tetanus.—Baisch has met with a cure of chronic relapsing tetanus, made evident by a contracture of the leg, which the writer supposes due to a condition of hyperexcitability of the ganglions. Intraneural injection of the antitoxin of tetanus, likewise intraspinal administration, resulted in a cessation of the contracture. Lumbar anesthesia with stovaine only decreased the intensity of the contracture. Deep narcosis did not cause the slightest muscular resolution, although it was carried out until a complete flaccidity of the upper limbs had been attained. The injection of novocaine had a marked influence over the hyper-tonus.

Adrenalin in Wound Treatment.—A. Wildt uses an ointment of boracic acid, to which he adds one, two, or three drops of a 1:1000 adrenalin solution to each 5 grammes of ointment. The results obtained were a decrease in proliferation of granulation tissue, narrow cicatrices and a diminution of the wound secretions.

Modern Views of Muscular Tonus.—E. T. von Brücke points out that the question of the origin of muscular tonus is not as yet physiologically elucidated. Hyper-tonus from decerebration, as demonstrated by Sherrington, is certainly not a phenomenon of the same kind as the tonus during rest. In the same way tetanic contracture is not to be compared to muscular tetanus. Quite on the contrary, the study of the phenomena of metabolism and reactional electrical current shows that the muscle in tetanic intoxication is not in a state of paresis, although it is contracted. In the case of certain unstripped muscles (such as the erector penis in dogs) it is nevertheless proven that the tonus results from the sum total of continued excitations, and belongs to a tetanus with more or less subintrinsic contractions. (To be continued.)

The Pathogenesis of Hemorrhagic Typhoid.—P. Kaznelson records three cases of typhoid fever with hemorrhagic tendency and an extreme thrombopenia. The variations in the hemorrhagic parous state are closely related with the fluctuations in the number of blood plaquettes. This condition cannot be attributed to an insufficiency in the genesis of the plaquettes, but to a thrombocytolysis which Kaznelson has observed in the spleen in one of his cases. The bone marrow reacts to this lysis of the blood plaquettes by a great increase in activity, which is met with in ordinary typhoid fever as well as in the hemorrhagic types.

How Typhoid Immunity Should Be Regarded.—Arneth, taking into consideration the writings of Liebermann and Accl, in which these writers opine to the belief that the immunizing properties do not exist in the

blood, but rather in the tissues themselves, that is to say, in a change of vital nature, endeavors more precisely to define these notions. Acquired immunity is certainly a function of the protoplasm, but it is unquestionably closely related to the blood cells as well, likewise to the splenic parenchyma and bone marrow. The writer concludes that from these data one should attribute to the blood the part that it really plays in immunization.

The Introduction of a "Practice Year" into the Program of Medical Studies.—I. von Hochenegg has found that the fact of obtaining the diploma of M.D. is quite insufficient for medical purposes, and that the holders of the parchment are in most cases useless as far as actual practice is concerned.

Hochenegg therefore advises a year's hospital practice for each student before graduation as a supplement to his theoretical knowledge. (This rule of one year's hospital practice was adopted some years ago in France, where it is called "stage d'hôpital.") It is a well-known fact that both German and Austrian students have been poorly instructed in practical work. In Switzerland the clinical instruction, which lasts for three years at least, is very carefully carried out, while in the United States the post-graduate teaching covers the deficiencies existing in any of the medical schools in respect to clinical instruction.

The Psychotherapy of Insomnia.—L. Stein believes that insomnia is closely related to a hyperexcitability of the cortical cells, which are, in turn, favored by special circulatory conditions. Insomnia reacts very badly on the patient's mental condition, inspiring great mental anxiety, and even causing a durable psychic depression. To overcome these divers conditions Stein employs persuasion. He shows his patients that sleep is not so essential as they are led to suppose. By thus convincing the patient as to the little importance of his insomnia, the necessary mental condition is wrought for the re-establishment of the lost function. However, it is to be particularly noted that Stein undoes all that he desires to accomplish by psychic treatment by exhibiting narcotics, although without the patient's knowledge.

False Perforating Bullet Wounds.—A. Schönfeld, under this mystic heading, relates to some cases in which there was only an entrance aperture of the bullet. However, the missile could be located in the submucosa of a viscus. Such localizations should be detected, because they require a special treatment, namely, to be left *in situ* since their ultimate elimination will take place spontaneously *per via naturales* after perforation of the mucous membrane takes place, thus setting the projectile free in the lumen of the hollow viscus. The same condition of affairs may occur in the mouth.

Traumatic Shock in War Surgery.—Quénu writes on this subject from the angle of the French surgeon, to whom the word has a different meaning than to the Englishman. What is called by the name may be primary or secondary. We may also speak of shock as something immediate, under which we understand the consequence of a nervous adventure or a profuse hemorrhage. A sudden intoxication produces a shock-like state, and after extreme fatigue and exposure to cold we see phenomena which suggest those of shock. In any condition whatever which is characterized by arterial hypotension, rapid pulse, lowered temperature, pallor, insensitiveness, etc., we may speak of the presence of a shock component. Shock, then, is thought of in etiological terms. In this connection stress is laid upon toxemia states (without any septic component), which result after wounds from absorption of wound products. In such cases we should at once suppress the focus—even in some cases to the extent of amputation; although such treatment has not heretofore been regarded as rationally indicated. Shock has been too much regarded as an entity and the hundreds of experi-

ments recorded do not seem to have taught us much of practical value. The subject is largely treated as a physiological one, and each physiologist has his own pet theory. The author, with Roger and other distinguished Frenchmen, insist that shock cannot be regarded as an entity, but only in connection with the particular causal type. There is no doubt that in all shock there is inhibition, and all inhibitory phenomena may enter into shock. The latter should be understood purely as an effect, and neither as a starting point or a mechanism. A uniform treatment is impracticable. A man with his temperature greatly lowered by exposure to cold is comparable to one in traumatic shock, but a single set of remedies intended to restore his temperature constitutes the entire treatment. This element of therapy also enters into the treatment of shock in general. Yet we cannot explain just how this resource can overcome shock. In immediate shock from hemorrhage one is supposed to make good the loss by the injection of saline infusion, but in practice, save in the exceptional case, the only thing done is hemostasis. In psychic shock from material or moral causes the chief etiological factor in the present war is wounds of the thorax, or abdomen. When the cranium is injured or a shell bursts close to the head we may imagine direct injury to the brain cells, as shown by Crile. It has been shown that in wounded who are examined soon after injury shock is rare. Operation on the recently wounded, however, adds to shock symptoms, notably lowering the blood pressure. Symptoms from toxic absorption do not supervene before 6 or 7 hours, and in mild cases 12 to 24 hours may elapse. In purely nervous shock one should forbear operation as long as possible in the hope that the lowered blood pressure will recover itself. In hemorrhagic shock one should effect hemostasis at all hazards, ligating all large trunks, giving only adrenalized serum. The question of post-operative transfusion is left open. In toxic shock the question is narrowed down to amputation to save life, or if the subject cannot withstand operation something may be done by local incisions and the free use of antiseptics, as formol and guaiacol. Secondary or delayed shock is a problem in itself, and a difficult one.

Revue médicale de la Suisse romande.

January, 1918.

The Clinical Forms of Uremia.—Hein and Tchertkoff isolate three radically different types of so-called uremia, as follows: Type 1, chloruremia, or eclampsia, essentially a convulsive state. The symptoms, aside from frequent convulsions, are headache, prostration, loss of consciousness, post-convulsive somnolence, etc. The début is sudden, and there are none of the petty evidences of uremia. Arterial tension is not notably high, the heart's action is sufficient. Transient paresis may follow the convulsions. Opposed to this picture is azotemia, with slow, progressive début, and in some cases petty signs of uremia. There are relatively few convulsions and post-convulsive phenomena, but headache, prostration, and drowsiness exist, with amaurosis, as in type 1. The heart is always hypertrophic, with blood pressure high; eventually there is cardiac insufficiency. Pericarditis often develops. Type 3 is the so-called false uremia. Patients are over 40, with arteriosclerosis and high blood pressure. The cerebral symptoms comprise vertigo, agitation, mental confusion, etc., the début being sudden. Convulsions are absent, but in this type the petty signs of uremia (Dieulafoy) are almost constant. Of these three types azotemia or true uremia of authors is best known as accompanying slow destruction of the kidneys. Chloruremia corresponds to the acute uremia of old clinicians, and to renal eclampsia. Its chief characteristic, aside from convulsions, is edema, associated with chloride retention. The cerebral symptoms may be attributed to edema of the brain. The condition is essentially amenable to cure. The renal lesion may be a nephrosis (as in mercurial poisoning), or an acute or subacute infection, as seen in scarlatina. The edema is especially prone to occur about the face and neck, and may be associated with hypertension of the cerebrospinal fluid. The convulsions cannot be brought into relationship with vascular hypertension. Pseudouremia corresponds to the

arteriosclerotic kidney, which is or is not a nephritis, according to the point of view. The numerous and equivocal phenomena known as petty uremia prevail here, and include eryesthesia, dead finger, cramps in the calves, muscular twitches, muscae volitantes, etc., which are all symptoms not of uremia but arteriosclerosis. The kidney parenchyma is intact, and does its work well—no waste products are held back in the blood. The only part of the organs damaged is the vascular system. Several clinicians discriminate between a benign and malignant renal arteriosclerosis. The latter is evidently attended by renal atrophy, hence nothing more than an advanced stage of true uremia. Mixed forms must occur—for an example, a case of incipient renal arteriosclerosis may be complicated by an acute or chronic nephritis. But little is said in the article of puerperal eclampsia, but certain cases of the latter agree closely with so-called chloruremia. On the other hand, eclampsia in pregnancy, with few or no convulsions, and without renal lesions, seems to stand in no relationship whatever with any form of uremia.

Hygiea.

January 16, 1918.

Serotherapy of Scarlet Fever.—Kling and Widfelt relate the following episode: From September, 1916, to August, 1917, a malignant epidemic of scarlatina prevailed at Stockholm. Of 2165 reported cases many were of very severe type, and there was a large amount of convalescent serum available. This was obtained from the fourth to the seventh week of the disease, and 0.5 per cent of phenol was added. The serum was only taken after negative Wassermann tests, and was always shown to be sterile by culture tests. It was used only in cases in which death was threatened. The criteria were symptoms of violent intoxication, with bad mental state; pulse 140-160, cyanosis, fever 40°-41° C. In this type of case the salvage would be much less than 50 per cent., unless some remedy could be found. Of 237 cases serious enough to receive serum 195 recovered, 25 died in the first and 17 in the second week of the disease. Of the 195 cures 101 were prompt and attended with notable defervescence—from 2°-4° C. in 24 hours, or less, without subsequent rise. The mental state became clear and the pulse normal, while cyanosis vanished. Of the remaining cases 80 did not show this rapid radical improvement, because of the pressure of complications—necrotic angina, lymphadenitis, otitis, etc. In this series recovery was gradual. There was no case of serum disease. Serotherapy dated from the middle of November, but was not applied wholesale until December. The severe cases began to increase in numbers after the epidemic was under full momentum, so that the influence of serotherapy was doubly manifest. In January, 1917, but 6.3 per cent. of the severe cases were lost, but this was exceptional. Of a total of 237 severe cases treated the mortality in all was 17 per cent., while in 91 of the same type who received no serum the mortality was 70 per cent. It was learned that a benign case of the disease can supply a serum of the same power as is formed in a severe case. A serum taken at the fourth week, and one from the seventh week, show equal power. The period at which the serum falls off in power has not yet been determined. Naturally the serum should be exhibited at the earliest possible moment. If no four-week-old serum is available serum of two weeks is known to be efficacious. In other words the antibodies are quite stable and differences in activity, if any, must be due to differences in quantity. Serotherapy does not prevent nephritis, and the ordinary suppurative complications are only slightly cut down in frequency.

Prochownik's Diet in Obstetrics.—Prochownik many years ago introduced a diet plan for gravidæ with narrow pelvis designed to diminish the measurements and increase the plasticity of the fetus. During the war it has been noticed that underfed women bear large children, but the author insists that fasting and dieting are quite different propositions. He recently employed his regimen in the case of a gravida who had previously borne a 3500 gm. infant and the child weighed but 2600 gm.—*Zentralblatt für Gynäkologie*.

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, March 13, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

THE evening was occupied with a symposium on pneumonia.

The Bacteriology and Serology of Pneumonia.—Dr. JOHN A. KOLMER spoke upon this phase of the subject. He observed that lobar pneumonia ranked next to tuberculosis in death rate and was endemic throughout the entire world. Certain races, notably the South African black, were known to be more susceptible to the disease. Raw recruits in the army were particularly subject to lobar pneumonia. This had been his experience with the troops on the Mexican border a year or two ago. Ninety per cent. of the condition clinically diagnosed as lobar pneumonia in adults was definitely known to be caused by the pneumococcus. The more carefully cases were studied, however, the more convincing were the deductions that the same organism was responsible for the remaining 10 per cent. Of the way in which the pneumococcus produced the pneumonia the knowledge of the investigator was limited. Careful blood pressure work showed that in about 50 per cent. of cases the pneumococcus might be found in the blood, but whether it first entered the blood stream by lowering of vitality and exposure to cold, localizing by tissue selection, or was transmitted through the alveolar spaces from the nose and throat was still an open question. The mode of the experimentally produced pneumonia in the laboratory bore no analogy to the knowledge of the disease in the human being. The symptoms of lobar pneumonia included not only the local disturbances produced by the filling up of the lungs with exudate but it was said to be also possible that the pneumococcus by disintegration liberated a poison within the bacterial cell which, entering the circulating fluids of the patient, produced intoxication. In addition to the toxins produced by the pneumococcus it was, in Dr. Kolmer's opinion, highly probable that part of the clinical picture of pneumonia was due to the absorption of products from the inflammatory exudate. The author's experiments during the past year would indicate that the exudate filling the alveolar spaces contributed a poison which played a part in the symptom complex of lobar pneumonia. There was also found in the urine of pneumonia patients a product of the pneumococcus. Of the classified types of pneumococci Type IV was generally found in the mouth of normal individuals and was less virulent than the others. Type I, which was highly virulent, produced about 33 per cent. of lobar pneumonia cases, particularly in this part of the country. The same percentage was accredited to Type II. Type III caused about 13 per cent. and Type IV 20 per cent. In children these percentages were somewhat different, but knowledge here was incomplete because of difficulty in obtaining sputum for diagnosis. According to the work done thus far Type IV caused the largest percentage of pneumonia among children. Based upon a series of four or five hundred cases, the relation of mortality in Type I, it had been shown, was about 25 per cent.; in Type II, 32 per cent.; in Type III, about 45 per cent., and in Type IV, 16 per cent. Cases showing the pneumococcus in the blood stream gave the gravest prognostic outlook. Attention was called to the fact that the dust of bedrooms in which lobar pneumonia patients had been treated contained the pneumococcus in from 50 to 60 per cent. of instances. From the standpoint of public health and of the epidemiology of lobar pneumonia Dr. Kolmer thought it of particular importance that the disease be regarded as an acute infectious disease, due to the introduction of a germ from without similar to the production of diphtheria by acquiring a virulent diphtheritic germ. The disease, he said, was very properly regarded as reportable, and in certain large cities of the United States lobar pneumonia patients were quarantined. There seemed to be sufficient information to warrant the physician in regarding his patient as a potential focus for the spread

of the disease. While not all cases could be traced to contact with the previous one, studies indicated that there were carriers of the virulent pneumococci, that patients might be carriers, also those in attendance upon them.

Symptomatology and Diagnosis.—Dr. ROSS V. PATTERSON said that pneumonia of typical type offered no diagnostic problems to the practitioner of even short experience. In his opinion possibly 80 per cent. of croupous pneumonia cases ran a typical course and were characterized by easily recognized symptoms and demonstrated physical signs. It was in the remaining 20 per cent. that the diagnostician found opportunity for the exercise of his art. In studying the clinical picture of pneumonia it was to be remembered that the disease was one of protean manifestations with many divergences from type. There was not a single symptom usually seen which might not be absent, and in some forms of the disease the majority of classical signs were absent. Symptoms were said to be dependent upon the infection, toxemia, extent and distribution of the lesions and upon the individual and his personal peculiarities. In children, apex pneumonia was apt to be attended with symptoms suggesting meningitis and such diagnosis in some cases had been made. In double pneumonia it was usual to find that one lung was invaded one or two days after the first. This second invasion was not as a rule attended by chill, nor necessarily with increased toxic symptoms. There seemed to be no very definite constant relationship between the extent of involvement in the lungs and the general constitutional symptoms. In massive pneumonia the lungs became completely airless and the physical signs simulated somewhat those of pleurisy. Occasionally the lesions would pass from one part of the lung to another or from one part of the lobe to another, giving various stages in the same or in both lungs. In abortive pneumonia the onset was sudden and violent, terminating even after a course so short as two or three days. This was the type seen often in able-bodied men. In the asthenic form, on the other hand, the patient was overwhelmed by the toxins and symptoms resembling those of typhoid fever were present. The croupous pneumonia of childhood was characterized as different from that in adults, pseudolobar in type, and accompanied by markedly nervous symptoms, and often simulated meningitis. The character of pneumonia in the alcoholic was said to be dependent upon its occurrence in the steady drinker or in the subject of an alcoholic debauch. In the steady drinker the onset might be quite characteristic, although the tendency to the development of nervous and uremic symptoms at times complicated the clinical picture. After the alcoholic debauch the symptoms might assume those of delirium tremens. Mention was made also of the variations occurring in the terminal pneumonias in the course of chronic debilitating affections, such as tuberculosis, arteriosclerosis, diabetes, myocardial conditions in which the onset is not characterized by chill and the disease is often not recognized. Reference was made to the intercurrent pneumonias seen in the acute infections like typhoid, diphtheria, or influenza, probably due to the specific organism of those diseases and differing in type from the ordinary croupous pneumonia due to the pneumococcus.

Pneumonia in Childhood.—Dr. HARRY LOWENBURG, in discussing pneumonia in children addressed himself to the two types, bronchial and lobar pneumonia. With reference to diagnosis of lobar pneumonia, in his experience convulsions rarely occurred in the onset and he rarely saw chill; the child suddenly became acutely ill, more often with gastric disturbances than nervous phenomena. Physical signs were sometimes delayed for five or six days. He felt, therefore, that this class of case occupied an important position in relation to the so-called obscure temperatures found in children. It was important to note also that the signs of consolidation were not always in evidence early. He believed it high time that the profession discarded the term "central pneumonia," and also disregarded as a possible clinical entity "pneumonia without physical signs." Either the physician was unable to detect such signs or the case was one of some other condition. With reference to central pneumonia, so-called, x-ray studies had proven that most pneumonias in children

began as subpleural manifestations and that the auscultatory signs of consolidation did not appear until the consolidated area touched the hilus of the lung. The consolidated area acted as a transmitter of the sound from the trachea to the ear. Until this was made complete the signs of tubular breathing were likely to be in abeyance. Therefore, he believed physicians should no longer speak of central pneumonia. In the beginning of these cases most was to be learned by percussion, and the experienced clinician could "feel" a pneumonia. Abdominal pain was a very common symptom of pneumonia in children and a very misleading one in cases in which the physical signs were late in appearing. It had been his experience in at least three cases to be unable to decide between pneumonia and appendicitis, and he had splendid company in his dilemma. In the differential diagnosis, therefore, diligent search should be made for physical signs in the chest, and in hospitals speedy use should be made of the x-ray. It was important also not to neglect a rectal examination, by which method tenderness on the right side would frequently be demonstrated. In none of the cases, however, would there be certainty of diagnosis until the patient had recovered, been operated upon, or had died. In children the pulse respiration ratio was of no diagnostic value unless counted during sleep. The most important complication of lobar pneumonia, in his opinion, was fluid. In the presence of a diffuse area of impairment associated with a marked sense of resistance upon percussion, out of proportion to the degree of dyspnea, the diagnosis of effusion was probably correct. He regarded this phenomenon of vastly more importance than the changing of the level or the area of dullness with change of position of the patient. He believed that more children with lobar pneumonia were assisted on the downward course by over treatment and over stimulation than in any other way. He advocated a "masterly inactivity," carefully watching the case; and the adoption, as in his hospital service, of a four-hour interval. At the end of that time the pulse and respiration were recorded, the indicated medication was given, the patient was fed, and then let alone. The bowels, of course, should be opened daily. In bronchopneumonia the child should be put in a room with fresh air that was not too cold. He did not give stimulants in pneumonia, except perhaps just before the crisis, and believed rest to be the *sine qua non* in the conduct of patients. They should be given morphine or codeine when restless, provided there was no contraindication. He emphasized his conviction that rest and "masterly inactivity" would bring better results than would over treatment.

Treatment of the Pneumonias.—Dr. S. SOLIS COHEN explained that he had chosen the term "pneumonias" because almost every pneumonia patient presented a different aspect, and clinicians, bacteriologists, and pathologists had recognized certain quite distinct types of the disease. The policy of "masterly inactivity" which had proven so successful in pneumonia in childhood in the hands of the last speaker, he stated, had proved very disastrous in the hands of the majority of the profession in lobar pneumonia in adults. It had been shown by statistics that the mortality rate of pneumonia had grown progressively worse with the progress of medical science. Pretty much all over the country two years ago the policy of "masterly inactivity," or the expectant treatment, resulted in a death rate of 40 to 60 per cent.; whereas at the time Osler went over the statistics at the Pennsylvania Hospital, it was shown that under various methods of treatment the average mortality was about 25 per cent. In reference to the statement that every case of pneumonia began to die or recover from the moment of infection, Dr. Cohen observed that, while the process of recovery might be impeded, the process of death and decay might also be brought to an end and recovery aided. The same factors in treatment might be potent for evil or for good according to the intelligence with which they were applied. The patient should be carefully watched for the dangers likely to occur. Cold fresh air to the aged and to the alcoholic, in his opinion, was fatal, but for the average patient in good condition cold air as well as fresh air he regarded as beneficial. Fresh air was best obtained by putting the patient on the uncovered roof, covering the roof only when storms de-

manded it. The patient must be kept thoroughly warm in his bed. The serum treatment in Type 1 infection had proven better than any other treatment that had been used, and he believed the rate of mortality to be anywhere from 5 to 10 per cent. At Chattanooga he was told that one patient out of 31 died when treated with this serum. The polyvalent serum did not seem to be highly successful. The next form of specific treatment was that of the bacterins. The word "bacterin," Dr. Cohen stated, was not a proprietary term. It was introduced by him, coined by him, given to the profession by him, and to any manufacturer who chose to use it. He had seen the most contradictory statements in discussions upon the value of the vaccine or bacterin treatment. Then came the difference in type and the assertion that the vaccine to be useful must be specific. For the last three or four years he has been using the bacterins early with increasing frequency and he had for that length of time been prepared to say that they fulfilled the first Hippocratic rule—they did no harm. He claimed it justifiable to make experiments with a therapeutic measure which offered some prospect of success, provided it was known that it would do no harm. At Ft. Oglethorpe he had gone through the hospital which was under the care of Dr. Charles H. Smith and Captain Arthur Dare, with Dr. D. H. Bergey, assistant chief of laboratory. The organization and the work of the hospital were the best he had ever seen. Dr. Dare, with the consent of his superior officers, had put into execution at the hospital the treatment of the pneumonias with a mixed vaccine, and in more than 100 cases of lobar pneumonia treated with this vaccine the death rate had been less than 6 per cent. Midway between the vagueness and futility of the expectant treatment and the certainty of the specific treatment there was that to which Dr. Cohen had given the name of definite treatment. This consisted in the use of medicine and hygienic measures, not haphazardly, not merely after a period of "watchful waiting" for dangers to occur, but in a definite association for definite purposes and in advance of the dangers. It substituted preparedness for locking the barn door after the horse was stolen. It followed the doctrine of Jacobi who said before the Society before the days of antitoxin, "The great danger in diphtheria is heart failure." The time to treat heart failure, Dr. Cohen emphasized, was before it happened. The time to treat the dangers of pneumonia was before they happened. That had been the basis of the treatment which he had gradually assumed and to which he had given the name of the "definite treatment." It combined the use of fresh air, all necessary therapeutic measures, good nursing, and hygiene. Outside of Blockley, in a series of over 400 cases the mortality under this treatment had been less than 16 per cent. At the Jefferson Hospital, where the best results were obtained, the mortality had been less than 8 per cent.

DR. A. C. MORGAN said that the diagnosis of pneumonia should be made before the physical signs appeared. The earlier the serum or specific treatment was given the better was the hope for recovery. The previous history of the patient should be regarded, since it was known that pneumonia had a tendency to recur. A patient with such a history, developing marked coryza with prostration disproportionate to the symptoms, should be treated as a case of suspected pneumonia and be given the serum or vaccine dosage at once without waiting for physical signs. Frequent swabs of the nose should be made to determine as quickly as possible the strain. He remarked upon the apparent increase of the ether pneumonias within the past year. This he thought might be due to lack of care in operative technique, or possibly because of the tremendous need for ether throughout the entire world there had been some unintentional contamination in its manufacture. He thought the discussion of pneumonia might be summed up under its mechanical and toxic features. In a patient with a myocardial degeneration but little pneumonia, from a mechanical point of view was required to produce a fatal termination of the disease.

DR. JOHN F. SINCLAIR agreed with Dr. Lowenburg regarding the pneumonias in children and regretted that he did not lay more stress upon the prophylaxis of pneumonia in this class of cases. In his opinion, one

of the reasons for the greater frequency of pneumonia in children seen in the hospital and dispensary than in private practice was the neglect of the care of the nose and throat. If at the first appearance of coryza or pharyngitis the condition were treated he believed the incidence of pneumonia among children would be markedly decreased. He also believed with Dr. Lowenburg that central pneumonia was a term without justification in its use regarding the pneumonias of childhood. This might not obtain in the pneumonias of adult life. He would emphasize also the value of light percussion in eliciting the pneumonic area. The puzzling point of abdominal pain had been well stressed. The complication of otitis media, though not mentioned, had been found in a small series of cases of lobar pneumonia to have been present far in excess of 18 to 20 per cent.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 27, 1917.

Dr. GEORGE W. KOSMAK IN THE CHAIR.

Puerperal Sepsis Due to *Bacillus Aerogenes Capsulatus*.—Dr. GEORGE L. BRODHEAD reported this case. He stated that the patient, 30 years of age, married, was admitted to his service at the Harlem Hospital, on November 17, 1917. Aside from an attack of grip about a year ago, during which she suffered from sore throat, congestion of the nose, occipital headache, and dizziness, being sick for about two weeks, her past history had no bearing on her present illness. About two weeks before her admission to the hospital she suffered an attack similar to the one just mentioned. Three days before her admission she purchased 10 grains of aspirin, 10 grains of quinine, and 10 grains of cascara for this cold. The last menstruation was September 10, 1917, just nine weeks prior to her entrance into the hospital. Urination had always been regular until her present illness. She had not voided for two days prior to her admission to the hospital. She had had two children and two spontaneous miscarriages. Twenty-four hours after taking the drugs above referred to the patient began to bleed from the vagina. She complained of pain in her throat and abdomen. Three hours after she began to suffer this pain her husband noticed a change in the color of her face, lips, and neck. He said her face was red and he thought she looked like a person whose heart was failing. A physician was called, who prescribed some codeine and essence of pepsin. Twelve hours after the onset of her illness her husband noticed that her entire body was copper-colored. The following morning the condition persisted, and her physician advised her to enter the hospital. She denied any instrumentation, operation, or examination by the vaginal route. Her only complaint was a bad taste in her mouth, pain in the throat, and weakness. Physical examination at the time of her admission to the hospital showed the temperature 102.4 deg. fahr.; respiration 40; blood pressure 90 systolic and 60 systolic. The woman was dyspneic, with respirations rapid and shallow. She had an anxious, pinched expression and a peculiar sweetish odor coming from her mouth. She was rational and quiet, answering all questions promptly and intelligently. She had a deep copper-bronze Indian-like hue of the entire cutaneous surface. This color did not appear to be pigmentation of the skin, but impressed one as being an underlying color, as if it were in the subcutaneous tissues. This discoloration was diffuse and of equal intensity all over the body, excepting at the finger tips and lips, which were blue and cyanotic. This color did not disappear on pressure; there were no areas of mottling, and no elevations of the skin. Examination of the eyes showed the palpebral and bulbar conjunctivae deeply discolored, being a muddy brown in appearance, resembling a deep jaundice. The lips were cyanotic, dry and fissured, and their cutaneous temperature was lower than the cutaneous temperature of the rest of the body. The tongue was dry, heavily coated, and fissured. There was no atrophy or fibrillation present. The posterior wall of the pharynx was

dry, dark blue in color, and many petechial hemorrhages were present. Similar hemorrhages were found in the gums and hard palate. Examination of the chest showed the respiration thoracic in type, the right side expanding more than the left. A few fine crackling rales were heard over the left lung anteriorly, between the first and third ribs. The voice sounds and respiration sounds were somewhat harsher over this area. The heart sound at the apex was high pitched, slapping, accentuated, and snappy—quick to come and quick to go. A presystolic murmur was present, localized within the apex beat. This murmur was harsh and grating in type and was not transmitted. An occasional thrill, systolic in time, was palpable over the area where the murmur was heard. The apex beat was not visible; it was palpable in the fifth interspace 11 cm. from the midsternal line. Every eighth beat was feebler than the rest and at times inaudible. The abdominal examination was negative except for tenderness all over the abdomen on superficial and deep palpation. The uterus was anteflexed, slightly tender, and about the size of a two months pregnancy. The cervix was central, thick and soft; the external os was one finger dilated; the internal os was not reached. There was slight tenderness in both fornices. There was marked hyperesthesia and hyperalgesia of all the muscles of the body, particularly the large groups of muscles. The patient was pulseless throughout her entire stay in the hospital. Two ounces of chocolate-colored fluid were obtained by catheterization; this was alkaline in reaction, with a specific gravity of 1040. Albumin was present; there were many red blood cells and few white blood cells. The guaiac reaction was positive; bile negative. The blood count showed 3,000,000 red blood cells, 50,000 white blood cells; the differential count showed 90 per cent polymorphonuclears, and 10 per cent lymphocytes. The patient was placed on eliminative treatment and cardiac stimulants. About seven hours after her admission and 40 hours after the onset of the illness, she became restless and irrational, her abdomen became markedly distended, pupils unequal and dilated. She remained in this state for a little more than an hour and then died. Dr. Brodhead reported in detail the post mortem and pathological findings. Stab cultures of agar agar made from the liver and heart, under anaerobic conditions, two hours post mortem, and incubated for twelve hours showed the *Bacillus aerogenes capsulatus*. The postmortem findings showed the infection very widely disseminated. The uterus was enlarged, soft and the opened mucous membrane presented a shreddy dark green appearance. The secundines were still attached to the right side of the uterus; the fetus was not present. When the perietal peritoneum was raised up from the underlying tissues blebs formed filled with gas. The speaker said that this was the first case of the kind he had met with in his experience, but that Dr. Cassasa, assisting visiting surgeon at the Harlem Hospital, had seen two cases of similar nature in his necropsy work.

Dr. HERMANN GRAD said that those who had made a study of the *Bacillus aerogenes capsulatus* stated that it was not unusual to find this microorganism in the blood during the last hours before death. The bacillus might be found in the intestinal canal, although it did not give rise to any symptoms, but it was never found in the blood except during a short time before death. Dr. Grad related an experience which he had had with this bacillus in a case operated on for pyosalpinx. This patient did not do well after the operation. Two days after the operation several blebs appeared on her arm and shortly after blebs were found at the edge of the wound. At the end of forty-eight hours they had appeared all over her skin. This patient lived about six days. The abdomen was reopened and blebs found all over the peritoneum. In this instance there were no gas bacilli in the blood.

Dr. CHARLES S. CASSASA said he had occasion to see this case clinically, and he had seen two other cases of *Bacillus aerogenes capsulatus* infection at autopsy in which the characteristic copper color was present. From the appearance of this patient he suspected that the *Bacillus aerogenes capsulatus* was present, though he also took into consideration the possibility of an acute Addison's disease or thought it might possibly be a case of acute silver poisoning. He thought that

possibly silver nitrate had been used in an attempt to procure an abortion. One of the former cases which he saw about a year ago gave a history of instrumental interference. She stated that a physician had introduced a catheter into the uterus and later she developed this characteristic color. Thirty-six hours after the insertion of the catheter she showed the presence of the gas bacilli in the blood. This was just before death. The important point to remember was the copper color which was pathognomonic of gas bacillus infection. The prognosis was very grave and the pain terrific. He had watched this case for crepitation over the femoral vessel, but this patient had not developed it.

Specimen from an Autopsy Eighteen Months After Percy Cauterization for Carcinoma of the Uterus.—Dr. JAMES A. CORSCADEN presented this specimen. He stated that the clinical history of the patient showed that she had been in the hospital twice. Her chief complaint was metrorrhagia. Nineteen months before her death, after unusual exertion, she had a hemorrhage from the vagina, which was severe and continued for several days. Three weeks after this an operation was performed, consisting in the excision of a specimen from the cervix, ligation of the internal iliacs, a double salpingo-oophorectomy, and a Percy cauterization. The pathologist's report at this time stated that the specimen from the tube showed follicular cysts of the peritoneum. Specimens from the cervix showed carcinoma of the cervix. After five weeks' stay in the hospital the patient went home improved in every way. Sixteen months later, August 17, 1917, she returned to the hospital, and died on September 20, 1917. She stated that she had had backache from the time of her previous discharge up to three months before this admission (four months before her death) when it disappeared. The abdomen had gradually increased in size, and pain was severe all over the abdomen. The treatment was confined first to attempts to relieve the distention. This proved useless, and then recourse was had to the constant administration of morphine. The patient gradually became weaker until death supervened. The clinical diagnosis was carcinoma of the uterus and intestinal obstruction. The writer presented the details of the post mortem and microscopical examinations. The vagina was smooth and short and ended blindly in a small cauliflower mass which represented the former position of the external os. A sagittal section of the uterus failed to reveal any cavity. The uterine wall was quite hard, but contained a large quantity of muscle. Upon pressure a few drops of necrotic material could be squeezed from the cut surface. The rectum was quite difficult to open on account of the tortuosity of its lumen and the extreme constriction which occurred near its union with the sigmoid. Incorporated in the pelvic mass were many cysts of a simple serous variety, some of which were small, but several reached a diameter of 5 cm. The microscopical examination showed a typical epithelioma. The pelvic tissues about the uterus were also infiltrated with tumor. The neoplasm in the rectum was similar to that seen in the uterus. The anatomical diagnosis of this case was carcinoma of the cervix uteri, causing obstruction of the rectum, metastases to the peritoneum and lungs, acute cystitis, and multiple cysts of the peritoneum.

Dr. HOLDEN asked Dr. Corscaden how he would treat such a case today in the light of what he now knew in regard to the x-ray and radium.

Dr. CORSCADEN replied that he would employ radium. He knew of one patient now living and doing her own housework two years after the first Percy, eighteen months after the second Percy, and a year after radium was first applied, a poor showing for the Percy and a fine result for the radium. The upper part of the vagina was filled with scar tissue.

Dr. HERMANN GRAD said he had had but little experience with the Percy method of cauterization for cancer. He had had two or three cases with fair results, but after all the Percy method was purely a palliative measure for extensive carcinoma of the cervix. If one wanted to clean up a carcinoma prior to treatment with the x-ray or radium it might have a field. In some inoperable cases if the cauterization could do even as much as it had done in this case which Dr. Corscaden

had reported it might have a place in surgery. This patient improved and lived for eighteen months. The speaker stated that just recently he had seen one of the results of the Percy operation which brought out a point worth mentioning. This patient had a history of metrorrhagia only for four weeks; she claimed that she was absolutely well until four weeks ago. From such an experience as this it would seem that they had been too hard on the general practitioner, in blaming him for not bringing these cases to operation earlier. He did not see them earlier because they did not have any symptoms and did not present themselves. This woman had absolutely no symptoms and yet the vagina was simply a mass of cancer tissue; it was difficult to say whether she was a case for a Wertheim operation. However, he did an exploratory incision and found that she was beyond all surgical aid. He then did a thorough cauterization, which was followed by no reaction, and the patient was now very comfortable and doing nicely. On the other hand, he had had a case some six months ago, in which a cauterization was done and the patient seemed to be progressing favorably when, on the seventeenth day, she had a violent hemorrhage and died. This hemorrhage was the result of a slough into the iliac vein.

Dr. CORSCADEN, in closing the discussion, emphasized the point that in forming an estimate as to the value of such a procedure it was better to get the material on the table and then anybody who wanted to could study it and draw his own conclusions. It might be that Percy was right in following Vidal in holding that low grades of heat retarded the growth of epithelioma more than they did that of normal tissue. The laboratory findings in this respect were absolutely contradictory. It seemed to him that if a woman had only a year or two to live there was no use in making her miserable for three or four weeks with the Percy procedure. There was also, with the Percy method, a certain mortality to be considered, while with the radium treatment there was no mortality. There might, however, be cases in which it was advisable to use the Percy method before employing the radium. With the use of the radium it is only necessary to keep the patient in the hospital a few days.

Pelvic Floor Repair During the Puerperium.—Dr. A. J. RONGY made this contribution. He said that his reason for bringing this subject before the Section was simply to stimulate a certain amount of discussion on a subject which had been entirely neglected in their work. Primary repair of the pelvic floor was a failure in a large percentage of cases no matter how carefully it was done. The problem which they had to solve was how to best repair the pelvic floor in a woman who had had three or four children and in whom the pelvic floor was relaxed and who was unable to stay in a hospital for any length of time owing to the fact that she could not leave her household duties and her children. If this repair could be effected while such a woman was in a hospital for a confinement it would be doing a great deal for her. Thinking along this line he had decided to try making the repair during the puerperium, and a number of suitable cases had come under his observation. Dr. Rongy reported six of these cases in detail. Most of these cases had both cystocele and rectocele. The operations were performed on the seventh or eighth day post-partum. The patients had made good recoveries and there had been no recurrence of the cystocele or rectocele. The technic of the operation was precisely the same as that followed in the secondary repair of the perineum or cervix, and one could employ the operation which he was accustomed to doing and could perform most successfully. The bleeding at seven or eight days post-partum was likely to be more profuse than at other times; hence one must be careful lest he strike large veins, or if he did cut a vein the bleeding must be controlled very quickly. The tissues had to be handled more carefully at this time as they were more friable than usual at five, six or seven days post-partum. The only danger involved was the danger of embolism if one happened to open up a large vessel. First, however, in his work of fifteen years said he had never encountered a case of embolism from this cause. It seemed to the writer that if they would take up the subject of pelvic floor repair during the puerperium for those women who were not able to come back for a

secondary operation, it would be a great advantage to such women. It would be advisable to work up three or four hundred cases of this kind so that they would have some criterion by which to go. The operation for the repair of the pelvic floor was primarily an obstetrical operation and should remain in the hands of the obstetrician.

Dr. BRODHEAD stated that his experience in work of this kind had been somewhat limited. He had had two or three cases of repair of the perineum in which he had done the repair seven or eight days after labor. These patients all did well, and he was inclined to believe with Dr. Rongy that there was a place in charitable institutions and among women who could not leave their homes at any other time for reparative operations of this kind. If, however, the patients could come back later, he doubted very much the advisability of operating just after labor. He felt that we must recognize that there is a certain amount of danger attendant upon operations at this time and that the thing to do was to tell the patient that there was a certain amount of danger and allow her to decide for herself.

Dr. HARRY ARANOW described a case in which a woman was having trouble from a bilateral tear of the cervix which she wished to have repaired after labor. He sent the woman to the Nursery and Child's Hospital, where she was delivered of a premature baby. He had told her that he would not operate at that time, that she would have to come back later. The patient urged him to operate, and having heard of what Dr. Rongy was doing he finally did a modified Sturmdorf operation on the sixth day post-partum. He did the operation very gently, not exerting any traction on the uterus so as not to interfere with the clotting in the uterine wall. The result in this case was as good as in any case of his that he knew of. Since that time he had a second case in which he did a low amputation of the cervix, a perineorrhaphy, and an operation for cystocele during the puerperium, and the results were as good as though the operation had been done under other conditions.

Dr. GEORGE W. KOSMAK said he had given this subject a great deal of attention and he could not bring himself to believe in the contention that the results of a primary perineorrhaphy were generally bad. As soon as they gave more attention to doing a primary perineorrhaphy they might expect to get better results. He said that it was a mistake to bind the legs of the patient close together after a primary perineorrhaphy, for by so doing the lochia was dammed back in the vagina and, decomposing, was more likely to infect the perineal wound. In order to avoid this it was his practice to keep the legs separated after doing a perineorrhaphy after labor, as in this way the wound could be kept cleaner. Dr. Kosmak also disapproved of the vulvar pad in such cases, and stated that where there was a free discharge the pad should simply be placed under the patient. He had no objection to the use of a douche and directed the nurse to give the patient a saline douche forty-eight hours after a perineorrhaphy had been performed. He also avoided a bowel movement in these patients, if possible. In these operations on the perineum he used only plain catgut and had no trouble with it cutting through and it was not absorbed before healing was complete. He thought the 50 per cent. bad results reported by Hirsch could be reduced. He had been getting 75 to 80 per cent. good results in primary perineorrhaphies. While he had not seen the results of doing the intermediary operation, he did not think it advisable to operate on a puerperal case within a week after labor if it could be avoided.

Dr. FREDERICK C. HOLDEN spoke in favor of primary perineotomy and said he would like to have the opportunity of demonstrating the difference in the women in whom a primary perineotomy was done and those in whom it was not done. After a perineum had been subjected to long-continued pressure and stretching it sometimes never regained its normal condition, and a primary perineotomy avoided this. He believed it saved many babies by avoiding the long perineal stage of labor. He did a perineotomy following the suggestion of Pomeroy, cutting to the anterior surface of the sphincter but not through it. He now encouraged his internes to do a primary perineotomy and avoid these operations for the repair of the pelvic floor.

Dr. BRODHEAD asked Dr. Holden whether he considered it an advantage to do a perineotomy in the median line rather than a bilateral perineotomy.

Dr. HOLDEN explained that the results in a bilateral perineotomy were not as good as those in a median perineotomy. Dr. Holden advised his hearers to try this procedure a few times and assured them that if they would do so they would not have the disappointment of having women come back after labor with the perineum all relaxed and everything prolapsed.

Dr. BRODHEAD asked if doing a perineotomy as Dr. Holden described made any difference as regarded the possibility of getting cystocele.

Dr. HOLDEN replied that it did not. The perineotomy was done after the head was on the pelvic floor. Dr. Holden said he never used a vulvar pad on a woman after he had repaired the pelvic floor following delivery. He placed these patients in the Fowler position and insisted on their lying on the abdomen for five minutes every two hours; this assisted in getting rid of the lochia.

Cesarean Section for Pregnancy Complicated with Cardiac Decompensation.—Dr. HARRY ARANOW reported this case, stating that his reason for bringing it before the Section was because his obstetrical management of the case had been severely criticised. He stated that the patient was a primipara, 26 years of age, who was referred to him on Oct. 10, 1917, in the thirtieth week of her pregnancy. She gave a history of having had scarlet fever, diphtheria, acute articular rheumatism, and one attack of heart disease with failure of compensation one year ago. The patient's health during pregnancy had been poor. She had had considerable nausea during the first two months. There was some cough with bloody expectoration at times. Urination was frequent during the day and two or three times during the night. The patient was markedly cyanotic and dyspneic; her lips and finger tips were blue. The dyspnea was so marked that she was unable to assume the dorsal position for examination. There was visible pulsation of the cervical veins. Examination of the lungs showed that respiration was rapid and shallow. There were moist rales at the base of both lungs. The heart beat was not visible at the apex. The beat was diffuse; the action tumultuous. No thrills were palpable. Percussion showed the heart enlarged to about five inches to the left of the median line and also to the right of the sternum. Auscultation revealed a double murmur, heard at the apex and transmitted to the left axilla and up toward the aorta. The apex beat was not distinct. The heart sounds had a gallop rhythm. The second pulmonic sound was accentuated. The pulse was 78 and the blood pressure 97-58. The diagnosis was pregnancy in the eighth month, mitral stenosis, mitral regurgitation, probable myocarditis, and failure of compensation. In consultation at this time it was decided that it would not be justifiable to add the burden of a labor or cesarean section to an already overburdened heart. Accordingly, the patient was admitted to the Lebanon Hospital for treatment by absolute rest and medication. As a result of this treatment the cyanosis and edema practically disappeared and the lungs cleared. The dyspnea, however, remained about the same. A consultation was then held with Dr. Rongy and several members of the medical division as to the best method in the further care of this patient. Dr. Rongy agreed with the speaker that a cesarean section would be the safest method of delivery in this case. The opinion of the medical internists, however, varied considerably. One man felt that we had no right to further endanger the mother's life by waiting for a viable child. Another man suggested waiting for a week or two, giving the patient a thorough course of digitalis medication, and then inducing abortion. A third internist gave it as his opinion that we could wait as long as necessary and allow the woman to have an easy labor. They waited until the thirty-sixth week of pregnancy, when the patient was given $\frac{1}{4}$ of a grain of morphine and 1/200 of a grain of scopolamine hypodermically at 8.30 A.M., and at 9.00 A.M., under light anesthesia, a classical cesarean section was performed and the woman delivered of a five and one-half pound girl baby. The patient stood the operation well. They quickly tied and resected both tubes and closed the abdominal wall. On top of the dressings and parallel

to the incision were placed two sand bags of about five pounds each. The mother was returned to bed in as good condition as before the operation. Both mother and baby did well; the mother went home comfortably on the fourteenth day post-partum. This case brought out the following points for discussion: Given such a case: (a) Was one justified in waiting for a viable child, or was it perhaps their duty to wait for a viable child? (b) Having reached the viable period, what was the best obstetrical procedure? (c) Were they justified in sterilizing the patient, or was it perhaps their duty to urge sterilization on the patient?

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

Clarksburg, November 21, 1917.

(Continued from page 662.)

BACTERIOLOGY AND HYGIENE.

1. Describe *B. tetani* and give its distribution.
2. Describe the morphology of the gonococcus and a reliable method of cultivation.
3. Name the conditions essential to the growth and development of bacteria.
4. Define (a) ptomaines, (b) leucomaines.
5. State what you mean by mixed infection and give an example.
6. State what you understand by (a) natural immunity, and (b) acquired immunity.
7. Describe the hygienic management of tuberculosis.
8. Describe the sanitation of a common school.
9. Describe several methods of purifying drinking water.
10. Describe in detail the construction of a sanitary privy.
11. Name the insect-borne diseases and the means for their prevention.
12. Give the hygienic management of measles.

PRACTICE OF MEDICINE.

1. Give treatment of cholera morbus.
2. Make a differential diagnosis of pleuritis and pleurodynia.
3. Differentiate pulmonary and gastric hemorrhage.
4. Give causes of typhoid fever and outline the prophylaxis. Give treatment, including diet.
5. Describe the symptoms and treatment of measles.
6. Describe the features of a case which would lead you to diagnose acute appendicitis.
7. Describe herpes zoster and its treatment.
8. Give the treatment of whooping-cough.
9. Give symptoms of acute spinal meningitis.
10. Of what diagnostic value is the knowledge of a patient's blood pressure?
11. What are the symptoms and characteristic findings in diabetic coma?
12. Give diagnosis of poliomyelitis and precautions to prevent its spread.

ANSWERS.

BACTERIOLOGY AND HYGIENE.

1. The *bacillus of tetanus* is a small, slender rod with rounded ends, and characterized by its peculiar spore, formed at one end of the bacillus and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It is from 2 to 4 mikrons long and from $\frac{1}{4}$ to $\frac{1}{2}$ mikron in breadth; it is slightly motile, and stains with the ordinary anilin dyes and by Gram's method. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube and produces gases.

Distribution, the soil, chiefly cultivated and manured fields.

2. The *gonococcus* is a diplococcus, the two cocci being flattened, and the pair facing each other and having a coffee-bean appearance. It is about $1\frac{1}{2}$ mikron long, and about 2-3 mikron in breadth. They occur both within and outside the cells, but are not found within the nucleus of the leucocytes. It is non-motile, does not form spores, is readily stained with the usual anilin dyes, and is decolorized by Gram's method. It grows upon human blood serum; also upon a mixture of meat infusion agar with ascitic fluid, hydrocele fluid or blood serum.

3. *Conditions essential to the growth and development of bacteria*: Most bacteria require proper temperature, generally at or near that of the body; oxygen is generally needed, those that cannot live without it being called aerobic, and those that can grow without it, anaerobic; nutriment of a proper kind, containing both organic and inorganic material; a slight degree of moisture; absence of bright light; a medium of slightly alkaline reaction, and rest. Individual bacteria may require modifications of some of these essentials.

4. *Ptomaines* are basic chemical compounds formed by the action of bacteria on organic matter.

Leucomaines are basic products produced in the tissues of living animals by cell metabolism.

5. By a *mixed infection* is meant the infection of a part by the entrance of more than one kind of pathogenic microorganism at the same time. Such a condition is often found when diphtheria bacilli in the throat are found accompanied by streptococci.

6. *Natural immunity* is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The chief conditions which give immunity are: (1) A previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

7. *Hygienic management of tuberculosis*: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine*.)

8. *Concerning schools*: The school building should be as near as possible to the center of the area which it is to serve; the site should be airy and open, of sufficient size, free from swamps, and somewhat elevated; it should not be too near factories, busy streets, or railways; the soil should be as free as possible from organic matter. The buildings should be so planned that the corners look towards the four points of the compass. In this way the sun will have access to each side and to every room during some part of the day. The building should have as few stories as possible. The walls should be of brick or stone, and should be pointed with cement; the inner surface of the wall should be cemented smooth. The foundations must be solid. The general arrangement will depend upon size of site, number of scholars, and number of required rooms. Fifteen square feet per child should be allowed. Details will have to be considered on: plans, accommo-

dations to be provided, shape and size of classrooms, distribution of rooms, teachers' rooms, corridors, entrances and staircases, playground, ventilation, heating, lighting, and placing of windows, sanitation, lavatories, water supply, drinking water, sewage disposal, removal of refuse, sanitary appliances, and drainage. Special care must be given to the prevention of contagious diseases and the exclusion of all possible sources of infection or contagion; there should be physical examination of children, also, for non-contagious physical defects.

The principal means of preventing the spread of contagious diseases in schools are: Regular and efficient inspection by physicians; prompt exclusion and isolation of any one suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

9. *The means of purification of public water supplies are storage and sedimentation, chemical treatment, and filtration. Sedimentation.* A part of the impurities in the water may be removed therefrom by storing the water in basins where the suspended matter sinks by the action of gravity, and in the process of settling entangles other impurities, as well as some of the bacteria in the water. In order to get good results, the basins must be shallow, the water left undisturbed, and the accumulated sediment removed from time to time. No complete reliance can be put on this method, as it does not guarantee a germ-free water. *Chemical purification:* The sedimentation of water in the basins may be hastened by the addition to the water of certain chemicals, which act as coagulants and form precipitates, entangling the organic impurities and bacteria, thus freeing the water from a large part of them. Alum (half a grain to the gallon), chlorine, bromine, copper sulphate, metallic iron, and ozone are used for this purpose. Neither sedimentation nor chemical purification is practicable for large water supplies, nor are they free from many objections. *Filtration:* This is the only method which has proved successful in providing a pure water supply. Filtration of large quantities of water is accomplished by means of sand beds of large area, the sides and bottoms of which are concreted, and on the bottom of which are placed numerous perforated and open drains which are to lead off the filtered water into separate special reservoirs. On the bottom of the filter areas, which are usually half or an acre in size, is placed a layer of coarse gravel, upon this a layer of finer gravel, which is then covered by a layer of fine, sharp sand, several feet in thickness, the whole filtering medium being from 4 to 6 feet in thickness. The filter is at first filled from beneath so that all air is driven off, and the filter area is then filled to a level of several feet above the filter bed. A filter of an acre in area may be made to filter two to four million of gallons of water in twenty-four hours. Such filters act not only mechanically in intercepting all suspended impurities, but the slimy sheet which soon covers the top layer of the sand acts biologically upon the water and destroys a large number of bacteria, so that, it is claimed, the water may be freed from 99 per cent of its bacteria, provided the rate of filtration is not too rapid and the top of the sand-layers is scraped off half an inch from the surface from time to time.—(From Price's *Essentials of Hygiene*.)

10. "The *privy* must be at least six feet away from any dwelling, and fifty feet away from any well, spring, or stream; ready means of access must be provided for the scavenger, so that the contents need not be carried through a dwelling; the *privy* must be roofed to keep out the rain, and be provided with ventilating apertures as near the top as possible; that part of the floor which is not under the seat must not be less than six inches above the level of the adjoining ground and moreover be flagged or paved with hard tiles having an inclination toward the door of the *privy* of one-half inch to the foot, so that liquids split upon it may run down outside and not find their way into the receptacle under the seat; the size or capacity of this receptacle may

not exceed eight cubic feet, by which limitation a weekly removal of its contents is necessitated; the sides and floor of this receptacle must be of some impermeable material, the floor being at least three inches above the adjoining ground level; the seat of the *privy* should be hinged so as to allow of the ashes being readily thrown in, and the receptacle unconnected with any drain or sewer.—(Notter and Firth's *Hygiene*.)

11. *Diseases transmitted by insects:* Typhoid, cholera, poliomyelitis, plague, tuberculosis, dysentery, anthrax, intestinal parasites, malaria, yellow fever, dengue, Texas fever, sleeping sickness, filariasis, relapsing fever, typhus.

To get rid of flies. Accumulations of dirt and filth must be removed or rendered distasteful to flies or larvæ by the use of lime, kerosene or cresol. Screens are used to keep flies out of houses; garbage must be disposed of in a proper manner; fly poisons such as arsenic or corrosive sublimate may be employed; fly traps are also useful; so, too, are fly papers.

To get rid of mosquitos. All pools, stagnant water, or places where the mosquitos may breed should be removed. Mosquitos and larvæ must be destroyed as far as possible. Fumigation by means of sulphur or pyrethrum will kill or stupefy the mosquitos, and in the latter case they can be swept up and burnt; mosquito netting and screens must be used.

Bedbugs may be exterminated by the use of formaldehyde or sulphur, absolute cleanliness, pyrethrum powder, and washing the floor and wooden bedsteads with emulsion of kerosene oil.

Fleas are exterminated by absolute cleanliness.

12. *Measles:* Isolation in a well-ventilated and darkened room; cool sponging or bath for fever; cool water to drink; if a sedative is required one grain of phenacetin may be given every three hours for four doses; if the cough is troublesome, three grains of sodium bromide may be given every three hours; inunction with 5 per cent. ichthylol in lanolin will relieve the itching; as a laxative, a quarter of a grain of calomel may be given every hour for two or three doses. The child must not return to school until all manifestations of the disease have disappeared. Fomites and "carriers" are common methods of spreading the disease.

PRACTICE OF MEDICINE.

1. *Treatment of cholera morbus:* A hypodermic injection of morphine sulphate, gr. $\frac{1}{8}$ to $\frac{1}{3}$ and atropine sulphate, $\frac{1}{120}$, should be administered, and repeated in half hour, if necessary. The various cholera mixtures (containing opium, camphor, capsicum, and rhubarb) are useful. Small pellets of ice will overcome the intense thirst to some extent, but liquids are contraindicated. Bismuth subnitrate (20 grains) and phenol (1/6 grain) may relieve the vomiting and purging. If the vomiting is very severe, an edema of choral (10 to 15 grains) in some demulcent, with 15 mm. of deodorized tincture of opium, will often relieve the patient. Locally, mustard leaves, turpentine stupes, and hot water bottles to the abdomen are of benefit. The after treatment consists largely in the regulation of the diet and a course of tonics.

2. *Pleuritis* is ushered in by chills; there is rapid rise of temperature, pain in side (made worse by any respiratory act), dyspnea, hurried breathing, quickened pulse, and distinct physical signs: Friction rub and fremitus; absence of vocal resonance and fremitus and breath sounds over the affected area, dullness on percussion; over the lung above the effusion there may be increased vocal fremitus and resonance, and Skodaic resonance; the apex beat may be displaced.

In *Pleurodynia*, there is no fever, no chills, no friction sounds, and no physical signs in general.

3.

HEMATEMESIS.	HEMOPTYSIS.
1. Previous history of gastric, hepatic, or splenic disease.	1. Previous history of pulmonary troubles.
2. Blood is vomited.	2. Blood is coughed up.
3. Blood is dark colored and not frothy.	3. Blood is frothy and bright red.
4. Blood may be mixed with food.	4. Blood may be mixed with sputa.

HEMATEMESIS.	HEMOPTYSIS.
5. Giddiness or faintness usually precede vomiting.	5. Sensation of tickling in the throat usually precedes.
6. Nausea and weight in epigastrium.	6. Dyspnea and pains in the chest.
7. Often followed by melena (black tarry stools).	7. Is not usually succeeded by melena.

4. *Typhoid is caused by the Bacillus typhosus.* It enters the body by the mouth, and is conveyed by food, fingers, flies, carriers, and fomites.

To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put in water or other drink or food. Prophylactic vaccination of exposed persons has been advised.

General treatment of typhoid fever: "As soon as the nature of the disease is recognized the patient should be confined to bed. The room should be large and airy, and provided with efficient means of securing thorough ventilation. The temperature of the room should be maintained between 65° and 70° F. The bedpan must be used from the beginning until convalescence is well advanced. The stools and urine should be rendered innocuous before being thrown out. This may be done by treating the evacuation with twice its volume of a 1 per cent. solution of chlorinated lime or a 5 per cent. solution of carbolic acid, and allowing it to stand in a covered vessel for two hours before emptying it into the closet. Soiled clothing should be thoroughly boiled. The diet should be liquid or semisolid, unirritating, and easily digestible. Milk alone (6 ounces every four hours) does not supply the required number of calories (2,500-3,000), but, as a rule, it should form a large part of the diet. It may be given diluted with lime water, or as buttermilk, malted milk, koumiss, junket, or ice cream. Among other suitable foods may be mentioned raw or soft-boiled eggs, chicken jelly, milk toast, strained oatmeal gruel, potato puree, tea, coffee, cocoa, fruit juices, wine jelly, and custard. Beef tea and broths may be harmful. In the event of digestive disturbances the diet should be restricted for a time to whey or albumin water. Water, plain or flavored (lemonade, soda water, etc.), should be given in large amounts between the feedings. When the first sound of the heart becomes weak and the pulse dicrotic, alcohol is usually indicated. From 4 to 8 ounces of whisky or brandy may be given in the twenty-four hours, the amount being determined by the general effect. The cold bath or the cold pack affords the best means of controlling fever and preventing the development of severe nervous symptoms. It may be employed every three or four hours, when the temperature is 102.5 F. or over. Hemorrhage, signs of perforation, menstruation, and great prostration are contraindications."—(Stevens' *Practice of Medicine*.)

5. *Symptoms of measles.* "After an incubation period of from ten to fourteen days the disease is manifested by a chill or chilliness, fever ranging from 101° to 102° F., muscular soreness, headache, and intense nasal, pharyngeal, and laryngeal catarrh. There are present also intolerance to light, redness and watering of the eyes, sneezing, and coughing. On the second day the fever remits to rise again on the fourth day, when an eruption of small, dark red, velvety papules arranged in crescentic groups appears on the face and soon spreads over the entire body. The catarrhal symptoms still persist. The eruption is attended by itching and more or less burning, and about the ninth day begins to fade

and disappear entirely by bran-like desquamation. All the symptoms then gradually ameliorate. Koplik's spots (a peculiar eruption consisting of small, irregular spots of a bright red color, with a bluish-white center, which appear on the mucous membrane of the lips and cheeks on the first day of invasion) are said to be pathognomonic.

Treatment: "Isolation, rest in bed, and protection from drafts and from bright light are necessary from the onset of the disease. It is often desirable to give a diaphoretic mixture. The bowels should be kept regular by means of some mild laxative. The diet should be semisolid. Mild cases require no medicines. Cool sponging or the following will reduce the temperature when it becomes alarmingly high:

R Tinct. aconiti..... $\overline{\text{mij}}$ to iv
Spts. ætheris nitrosi..... $\overline{\text{mxx}}$ to xv
Liq. potas. citrat. q. s. ad f 5j

M. S.—Every two hours.

Daily inunction of cold cream, cocoa-butter, eucalyptol in petrolatum, and similar oily substances will serve to relieve the itching of the eruption. Camphorated oil rubbed on the chest and applied to the nose and neck aids in lessening the catarrhal symptoms."—(Hughes' *Practice of Medicine*.)

6. *Diagnosis of acute appendicitis:* "When the three cardinal symptoms of the disease are present—that is, sudden onset of acute abdominal pain, followed by vomiting, occurring in one previously well; unilateral rigidity of the right lower abdominal wall; tenderness over the site of the appendix—the diagnosis of appendicitis is warranted in nearly every case. . . . Failures in diagnosis, however, may often be explained by the fact that the initial symptoms were insignificant, were lost sight of, or were obscured by the injudicious use of opium. The commencement of an attack of acute appendicitis may very closely simulate acute indigestion, in that there occur vomiting, colicky pains, often implicating the entire abdomen, and tenderness. But in acute appendicitis there is nearly always a certain sequence of symptoms—pain, vomiting, tenderness—and rigidity of the rectus muscle is nearly universal. If this sequence of symptoms—(1) pain, (2) vomiting, (3) tenderness—is altered, the diagnosis of acute appendicitis may well be considered doubtful; and where acute appendicitis is present and these symptoms have not occurred in the order described, other signs are generally present which render the diagnosis certain. Fever nearly invariably appears later than the three symptoms first mentioned. If hyperpyrexia occurs first, typhoid fever may be suspected, or pneumonia; if vomiting occurs first, acute indigestion or scarlet fever may be the cause; while where tenderness precedes the other symptoms for some hours or days, pelvic disease, or chronic intestinal ulceration are to be considered."—(Deaver.)

7. *Herpes zoster* is "an acute inflammatory disease, characterized by the development of groups of firm and distended vesicles situated upon inflamed bases corresponding to a definite cutaneous nerve, and accompanied by more or less severe neuralgic pains. The affection begins with neuralgic pains, either of a burning or lightning-like character, with slight febrile phenomena, followed by the appearance of papulo-vesicles along the tract of pain; these soon become vesicles situated on bright red, highly inflamed bases. The vesicles are about the size of pin heads, or, perhaps, a little larger; usually discrete, although they frequently coalesce, forming irregular patches, appearing in groups until the third to the fifth or even tenth day, when they gradually desiccate, and at the end of the second week nothing remains except occasionally a slight scar, which may disappear or become permanent. When the eruption is at its height it is perfect in its anatomic formation, each vesicle being well shaped and seated on a bright red, inflamed patch of skin, and distended with a translucent, yellowish fluid. The vesicles show no tendency to rupture spontaneously. In rare instances they may become purulent, hemorrhagic, or gangrenous. The eruption is almost invariably confined to one side of the body, although in rare instances it is seen upon both sides. It is usually found upon well-known nerve tracts. Recurrence is rare." The treatment consists in relieving the pain (by sodium salicylate or phenacetin, or, in severe case, by morphine). Zinc phosphide and nuxvomica have been recommended. Lo-

cally a dusting powder of boric acid or zinc oxide is useful; or collodion may be painted over the vesicles to protect them from injury.—(From Hughes' *Practice of Medicine*.)

8. *Treatment of whooping cough*: Isolation of the patient in a warm but well ventilated room; the throat may be sprayed with a two per cent. solution of resorcin or salicylic acid; chloral, or belladonna, or potassium bromide should be used as an antispasmodic; bismuth may relieve the vomiting; during convalescence tonics will be necessary.

9. *Symptoms of acute spinal meningitis*.—"There are two stages: the first, the stage of irritation; the second, the stage of paralysis of motion and sensation, with atrophy. Although an inflammatory affection, its onset is usually subacute, the febrile reaction being moderate, with intense boring pain in the back, aggravated by motion, rigidity of the spine, and a sense of constriction around the body—"the girdle." Spasmodic contractions of the muscles supplied by the nerves originating at the seat of the lesion, with inability to straighten the limbs are also present. If the lower part of the spinal membranes is the seat, there occur retention of urine and constipation; if upper part, dysphagia, dyspnea, and feeble heart. If the inflammation extends to the medulla, the above symptoms are associated with disorders of speech, vomiting, and delirium. The muscular contractions are excited or increased by motion, but uninfluenced by pressure. Reflex movements are not abolished. The rigidity and spasmodic contractions of the muscles are followed by paralysis, more or less complete, death ensuing as a consequence of paralysis of the muscles of respiration."—(Hughes' *Practice of Medicine*.)

10. **ABNORMAL BLOOD PRESSURE.**—*Pathological High Blood Pressure*.—"High pressure *per se* is not a disease but a phenomenon or symptom, which may accompany a great variety of diseased conditions, including diabetes, gout, syphilis, chronic lead poisoning, cardiovascular renal disease, many anomalies of nutrition, etc. *Acute asphyxia and acute anemia* of the brain (medullary centers) will powerfully stimulate the vasomotors, causing contraction of the splanchnic area and a rise in blood pressure. *Lead colic* affecting the abdominal vessels is usually associated with high blood pressure, as is also the early stage of peritonitis. *Pain*, even when slight, as in pinching the skin, usually elevates pressure. Continuous high pressure is seen in certain forms of nephritis. Thus in primary acute Bright's disease and in nephritis secondary to scarlet fever, there is practically always a marked rise in arterial pressure. A rise amounting to more than 50 millimeters Hg. has been observed within 48 hours of the onset of an acute nephritis. Elevated pressure is also found in beginning arteriosclerosis of the first part of the aorta and of the splanchnic vessels."

Pathological Low Pressure.—"A pathological depression in blood pressure may be caused by the depressing influence of circulating toxins, acting either upon the heart, blood vessels or controlling nervous mechanism or to sudden withdrawal of a large volume of blood from the circulation as in hemorrhage, after *venesection*, *copious diaphoresis*, *diarrhea*, or in *shock*. In general it may be said that lowered blood pressure is of little significance except after hemorrhage or during surgical shock. Here the great and sudden reduction in pressure may be sufficient to immediately endanger life. It is noted that a moderate and progressive falling pressure occurs in most progressive and prolonged fevers, as in typhoid fever. When due to such a cause the depression is rapidly overcome and disappears as convalescence is established. Widespread dilatation of the vessels and consequent lowering of blood pressure has been noted in the last stages of *arteriosclerosis*. (Krehl.)"—(Faught's *Laboratory Diagnosis*.)

11. *Diabetic coma* may be of sudden onset, or may be ushered in by headache or restlessness. Excitement and fatigue are favoring factors. The pulse is rapid and feeble, the temperature subnormal, the respirations prolonged and sighing; the patient is drowsy. His breath and urine have an odor like that of apples. The urine may contain acetone, diacetic acid, and beta-oxybutyric acid. The drowsiness passes into coma, and may end fatally. Usually in these cases there are no convulsions.

12. *Acute anterior poliomyelitis*. The early signs are fever, malaise, chilliness, tonsillitis, coryza, diarrhea, convulsions, profuse sweating, rigidity of head, neck and limbs, pain in neck or back, or there may be no early signs. There is sudden paralysis of one or more limbs or of individual muscle groups, and this is followed by rapid wasting of the affected parts, with reaction of degeneration and deformity. The lower limbs are chiefly affected.

To prevent its spread.—The patient should be isolated, in a room that is screened and free of hangings, etc.; urine, feces, nasal secretions and sputum must be disinfected; all implements and food that have been touched or used by the patient must be thoroughly cleaned; physicians, nurses and attendants must use the same precautions as they would in attending a case of (say) scarlet fever; gargles, sprays and nose washes of 1 per cent. solution of hydrogen dioxide should be used.

(To be concluded.)

Miscellany.

Various Systems of Ventilation Tested.—In order to arrive at some definite conclusion as to the advantages or drawbacks of different types of ventilating contrivances, the New York State Commission some years ago undertook to establish a criterion by which ventilation could be judged and the factors necessary to ensure adequate ventilation more definitely known. The report of this commission showed that too little importance had previously been attached to the movement of the air and to a proper combination of movement, temperature, and humidity. In some respects this report seemed to nullify the claims made for the surpassing importance of real fresh air. In order to obtain more concrete evidence of the value of fresh air, the Bureau of Child Hygiene of the New York City Department of Health in 1916 began an inquiry into the possible relationship between the prevalence of respiratory disease among school children and class room ventilation. This investigation was conducted among 5,533 pupils in 76 class rooms in 12 schools, under three different types of ventilation; the study covered a complete five-month period in the late fall, winter, and early spring.

The investigation formed the basis for the following conclusions: (1) In the closed window, mechanically ventilated type of classroom kept at a temperature of about 68° F., the rate of absences from respiratory diseases was 32 per cent. higher than in the open-window, naturally ventilated type of classroom kept at the same temperature (about 68° F.) and about 40 per cent. higher than in the open window, naturally ventilated type of classroom kept at a temperature of about 50° F. (2) In the closed window, mechanically ventilated type of classroom kept at a temperature of about 68° F., the rate of respiratory diseases occurring among pupils in attendance was 98 per cent. higher than in the open window, naturally ventilated type of classroom kept at the same temperature (about 68° F.) and about 70 per cent. higher than in the open window, naturally ventilated type of classroom, kept at a temperature of about 50° F. (3) The relative humidity of classrooms, whether ventilated by natural or mechanical means, was not a causative factor in the occurrence of respiratory illness among school children.

THE NARCOTIC DRUG ADDICT.*

By ERNEST S. BISHOP, M.D.,
NEW YORK.

CLINICAL PROFESSOR OF MEDICINE, NEW YORK POLYCLINIC
MEDICAL SCHOOL.

A NARCOTIC drug addict is an individual in whose body the continued administration of opiate drugs has established a physical reaction, or condition, or mechanism, or process which manifests itself in the production of definite and constant symptoms and signs and peculiar and characteristic phenomena, appearing inevitably upon the deprivation or material lessening in amount of the narcotic drug, and capable of immediate and complete control only by further administration of the drug of the patient's addiction.

In a paper "An Analysis of Narcotic Drug Addiction," read before this Society December, 1914, I stated: "In observing a number of addicts over a length of time, one cannot escape the recognition of a chain of constantly present physical manifestations inevitably following the non-administration of the drug. These may vary in priority of onset, in sequence, and in relative violence of manifestation in different cases, but they are the inevitable result of non-administration of morphine to a morphine addict. They constitute what are called the "withdrawal signs." To quote from a previous paper ("Narcotic Addiction—a Systemic Disease Condition," *Journal of the American Medical Association*, February 8, 1913): "In a general way they may be said to begin with a vague uneasiness and restlessness and sense of depression; followed by yawning, sneezing, excessive mucous secretion, sweating, nausea, uncontrolled vomiting and purging, twitching and jerking, intense cramps and pains, abdominal distress, marked circulatory and cardiac insufficiency and irregularity, pulse going from extremes of slowness to extremes of rapidity with loss of tone, facies drawn and haggard, pallor deepening to greyness, exhaustion, collapse, and in some cases death."

In plain English, a narcotic addict is one who experiences symptoms and signs as above outlined as a result of lack of supply or insufficient supply of narcotic drug. I know of definition along no other lines which will include all who suffer from narcotic drug addiction. This symptomatology and the mechanism or process which produces it are the only common and characteristic attribute and possession of all narcotic addicts.

How it is developed and how it may be controlled and arrested is the demand which the sufferer from

*Read at a meeting of the Medical Society of the County of New York, March 25, 1918.

narcotic drug addiction and which society as a whole is making of the medical profession. Until the medical profession can give competent and acceptable answer to this demand its other discussions will remain inconclusive and its other considerations incidental. This is the medical problem of narcotic drug addiction, and until the medical profession has recognized, is familiar with, and can to some working measure explain the physical phenomena and symptoms and signs of this condition, it is unprepared to assist intelligently and competently in the solution of a problem which now as never before menaces the welfare of society. They are the one constantly present set of facts in all narcotic addicts.

What type or class of individuals become narcotic addicts? Any type or class or individual to whom opiates are given for a sufficiently long time. It has yet to be demonstrated that there is any warm-blooded animal which, following sufficiently prolonged and constant administration of an opiate drug, is immune to the development of the above-mentioned symptomatology and the constant physical phenomena of which I have written elsewhere.

Color, nationality, social or economic position, age, mental and moral attributes of whatever sort are no bar to the development of the condition. These may influence of course the conduct and incidental manifestations of the individual addicted, just as they do in any other condition. The addicted judge, or the addicted physician, or the addicted clergyman, or the addicted man of business or other affairs, or the addicted clerk or industrial worker reacts differently to the suffering and trials of narcotic drug addiction from the addict of the underworld, or the heroine sniffer of idle and curious adolescence, or the addicted defective or degenerate or criminal. Also he reacts differently to everything else. What is true of one man who has narcotic addiction may be absolutely false of another. One narcotic addict is honest, competent, truthful, and intelligent. Another is dishonest, incompetent, untruthful and incapable of appreciation or self-control. Neither the one set of attributes nor the other is peculiar to narcotic addicts. They are simply personal attributes possessed by different men and types of men who may or may not be narcotic addicts. If the addict of the higher class displays at times attributes not typical of his pre-addicted days and seems to show a lowering of his mental or moral tone, it is well to estimate in his case the influences of past worry, and fear and suffering and strain and struggle, the attitude of society, medical and lay, towards him, and the manner in which he has been handled, before blaming it all upon the mere presence and action of narcotic drug

addiction. If such changes were inherent in the effects of a narcotic drug, they would be found in all addicts, whereas the fact is that they most decidedly are not found in all addicts. I have discussed this phase more fully in a previously published paper.

As to age in addicts there is no limit. I have seen an infant newly-born of an addicted mother. The infant must have developed the condition prenatally as it displayed the signs and symptoms of physical drug need, of which I have written above, a few hours after birth. There have been many such cases, some of which are matters of medical record. The condition exists beyond dispute and certainly cannot be explained upon grounds of conscious appetite or deliberate self-indulgence. I am told that in some of the homes for old soldiers are ancient veterans of the Civil War whose addiction dates from wounds received during that struggle. The late Dr. T. D. Crothers told me once that opiate addiction in this country received its first wide dissemination in that way. This points to the serious consideration of what may become one of the urgent medical problems arising from our present war.

As to the origin of addiction. There is only one actual origin of addiction, and that is the continued administration of a drug of addiction sufficiently long to develop the physical manifestations, symptomatology, and phenomena of body need for a narcotic drug. This statement is the only one which can be made as a generally inclusive announcement. I have many records and histories, much correspondence, and other data, collected from addicts, relatives, and friends and associates of addicts, physicians, official conferences, and workers in the various fields of narcotic endeavor. My material covers an active interest of many years' duration, and an experience which has dealt with various classes under various conditions. I have held different beliefs at different times, influenced by my own interpretation of experience, by the conditions under which I happened to be working, and by the class of people coming to my attention. At one time when in Bellevue Hospital I believed that all addicts were defective, degenerate, irresponsible, and unreliable, made addicts by curiosity, environment, or morbid appetite. That I believe is likely to be the attitude of the institutional physician, handling those who reach places of public custody and restraint. At one time I believed that the narcotic addict did not need the narcotic drug and could get along without it if he only had the will and the desire to do so, and that enjoyment lay at the bottom of his indulgence. I proceeded on that theory for a while in the handling of my cases, and have to thank the illicit supply which is present in all institutions that my mortality was no higher than it was.

The actual origin of addiction is administration of opiate drugs. The incidental details in the early administration to those who have become addicted vary widely. In the origin of the addict of the upper world, we of the medical profession must sooner or later come to recognize and to assume our part, unconscious and innocent but none the less beyond question. It is now beyond dispute that great numbers of cases of addiction received their

origin in medication during illness, the condition developing unsuspected alike by physician and by patient until its physical sufferings had passed the bounds of control.

The old fallacy that an opiate might be administered safely to a sufferer so long as the patient did not know what was being given has been responsible for many a case of addiction. Very many addicts have passed into the stage of fully established addiction symptomatology before they were aware that they had ever taken an opiate. A clinical familiarity with the symptoms and signs of beginning and developing addiction should be the possession of every physician and surgeon. It would save from the mental tortures and fears and from the physical suffering of narcotic addiction many human beings. It has been my experience when called in as a medical consultant upon medical and surgical cases whose progress toward recovery seemed unaccountably tedious and unsatisfactory to detect as the basis for the lack of function and recuperative power an unsuspected developing addiction in time to prevent its further progress. Unwisely prolonged narcotic medication makes more narcotic addicts than we realize.

This is one class of addict, the individual who is primarily normal, mentally, morally, and physically, and whose addiction condition is a result of ignorant, misguided, or unavoidable medication, either professionally or self-administered. Their number is far greater than is yet appreciated. Many if not most of them are unsuspected and unknown, and they include eminent people in all walks of life. They are social and economic assets whose interests and welfare we cannot ignore when we are considering the disposition and handling of the narcotic addict. They have gone from one institution to another, attempted in desperate effort each newly-discovered and announced specific or theory of treatment. They have never derived any pleasure from narcotic use. For them the narcotic drug has been only necessary medication to relieve physical suffering and to maintain economic existence and the support of themselves and their families. They should be classed as innocent or accidental addicts—normal and worthy sick people. They earnestly desire treatment and help, and once their addiction process is competently arrested do not tend to return to narcotic drug use. Whatever association they may have had with the unworthy or unfit so-called underworld and illicit and illegitimate traffic has been the result of desperate necessity in the obtaining of an opiate supply otherwise denied them, but, until practical methods of treatment and handling shall be generally known and used, necessary to them for the relief of suffering and for the maintaining of a condition making possible self-support and the avoidance of revelation and disgrace.

The narcotic addict of this class presents primarily and fundamentally a purely medical problem. Competent and complete arrest of the physical processes which cause the suffering of narcotic drug need permanently removes him from the ranks of the narcotic drug user. His problem is one of medical and nursing treatment and care. His after-care is simply such convalescence as is needed in the ordinary medical case to restore him

to physical efficiency. The length of his convalescence depends entirely, just as in other diseases, upon the competency and intelligence of his medical handling and upon his physical condition, reaction, and inherent recuperative ability. For such a man custodial care and institutional handling under conditions of enforced restraint are undesirable and harmful. His withdrawal from self-supporting citizenship should be for the shortest time commensurate with adequate therapeutic results. He should be restored to normal personal, social, and economic environment at as early a time as possible following his clinical treatment and the arrest of his physical mechanism of addiction. Given understanding clinical handling with comprehension and rational therapeutic recognition and meeting of the indications of disease in his case, he is no more a subject for restraint or custodial care than is a case of malaria or pneumonia. He is a clinically curable medical case.

A patient of this type will cooperate to the limit of his ability with the physician who is treating him, so long as he has faith in that physician's understanding of narcotic addiction and clinical familiarity with its symptoms and phenomena. It must be remembered, however, that the intelligent narcotic addict of this class possesses more clinical knowledge of drug addiction than any other class of men alive, and that he has been through before many procedures and treatments for which much had been promised, but which failed in result. He is skeptical and he is alert, and he will be the first to detect the shortcomings of the physician whose theories and practices do not accord with what the addict knows to be facts. The addict knows that the mere stopping or getting away from the opiate drug by whatever method or procedure is in itself a useless accomplishment unless coincident with it there comes cessation of the suffering, nervousness, sleeplessness, pains, and physical incapacity of continued and persisting low-grade addiction which he has experienced before, and which he knows to have been the condition which drove him back to opiate medication in desperate search for relief and working ability. The real condition to be considered and treated is not the use of a drug merely but the physical process whose symptomatology and suffering call for narcotic medication. Until this is arrested the patient will continue to suffer. Stopping the narcotic drug alone does not end the suffering and the addict knows it from previous experience.

I have given space to this type of addict because it is the type that demands and deserves of us as medical men clinical and laboratory study in the same broad spirit of scientific endeavor that is applied to other clinical conditions. This type of case is the as yet neglected job of our clinical and laboratory workers. There is a mass of tangible clinical facts to be observed and taught before we shall have fulfilled our professional duty to such cases. The answer will lie in no special specific medication or panacea, in no one definite or routine line of procedure. It will lie in the education of the physician into the clinical facts and manifestations of narcotic addiction, and their therapeutical control by such measures as are required to meet the indications of the individual case.

There are very many other cases, not falling within the class of narcotic addicts that I have been discussing, and in which the problem is not purely medical for the simple reason that the addiction condition exists in individuals whose types, characteristics, and environments make them in one way or another abnormal.

The degenerate, the defective, the high-grade imbecile, those of the hysteroid types, and some subjects of other psychiatric states are especially easy victims of curiosity and of suggestion, and readily fall through environmental influence into narcotic indulgence which persists until physical addiction is established. Once this is accomplished their future patronage is assured to the illegitimate trafficker in narcotics. The problem of their handling is quite a different matter from that of the type first mentioned. Narcotic addiction is merely one of the indications in the handling of people of this class, and the clinical arrest of the addiction process and addiction symptomatology is a minor accomplishment compared with custodial or correctional care and training for a considerable period of time. Their fundamental condition is not addiction, but is morbidity and irresponsibility of mind and life. Past experience in suffering and misery is quickly forgotten by them and has little or no deterrent influence upon their future conduct. They are without occupation and lack incentive to work. However competent and complete the medical and clinical treatment and relief of their addiction process, and however long the period of their subsequent restraint, they tend to seek a morbid environment to whose influences and opportunities they cannot react with adequate resistance. The members of this class are primarily and fundamentally problems for the alienist and for the custodial and correctional authorities. The disposition and handling of this class subsequent to their medical care is of vastly greater importance than the medical treatment of their physical addiction, not because they happened to have become narcotic addicts, but because of their fundamental characteristics and mental attributes.

There is one other class which has been and is growing with frightful rapidity during the last few years under the conditions which have fostered and made profitable the development of illicit and illegitimate narcotic drug traffic. This class is composed of those who, though not fundamentally defective, degenerate, or vicious, are not trained or educated or developed to resistance to environment or to associates. There has been a great increase of young narcotic users, victims of the instability, curiosity, excitement, and sensation seeking, associated with the developmental period of adolescence. They are simply young, untaught, inexperienced, and adventurous, easy victims for the recruiting agents of illicit traffic in narcotic drugs. Their problem is medical, custodial, educational, and sociological. We owe them medical relief and sociological and educational attention and training. We owe it especially because ignorance and misconception as to addiction facts and neglect of conditions and widespread education laid the basis for the illicit traffic of which they are the victims.

From the foregoing it will be readily seen that the only attribute common to all addicts is the de-

velopment of addiction symptomatology and phenomena. If we are to try to help the addict, the clinical and laboratory study of that symptomatology and phenomena is our fundamental medical duty. There have been many theories offered in explanation of it, and with awakening interest in the subject there will be many more. Each theory and explanation will probably add something to the information possessed, and will turn out to be partly wrong and partly right. None yet offered contains the whole truth nor an absolutely unassailable explanation of all the manifestations of the condition. It is probable that no one theory can possibly do so. Certainly no one of them should receive off-hand acceptance and credence at the present time. The condition is too complex and too varia-

ble in its clinical and pathological problems, and men of equal honesty and ability hold widely diverging beliefs. frequent discussion the various workers in the field. We are all partly wrong and partly right. There is no one of us who cannot learn from any one of the others. The real end of effort is not to prove one or another of us right, but to take each from the other whatever is of value, and all to contribute in true scientific spirit of broad tolerance toward the ideas of others and of willingness to correct or modify ideas and theories of our own, searching for no panaceas or specifics, simply hunting for truth wherever we may find it.

There is too much work to be done and the situation is too urgent for remedy to permit of longer delay in scientific approach. Under present conditions, no man's announcement of theory or of remedy is to be taken as ultimate authority, but simply

Sphygmographic Tracings showing the Physical Organic Dependence upon Opiate Administration in the Circulation of a Narcotic Drug Addict

Patient convalescent from pneumonia with persisting sequelae of marked circulatory deficiency which did not respond to the administration of the usual circulatory stimulants even in large doses. I was called in consultation.

Found patient to be a narcotic addict of many years standing, his addiction developing as a result of physician's medication during illness.

During recent pneumonia and subsequent to it, morphine had been administered in therapeutic doses for relief of pain, restlessness and sleeplessness. The daily average of such medication just prior to these tracings was about one-half grain a day. The last dose prior to these tracings was one-eighth of a grain given at 3:30 p. m.

I first saw the patient and made No. 1 tracing about 6:00 p. m.

Tracings No. 2, No. 3 and No. 4 were made at about 15 minute intervals. They were made following experimental hypodermic injections of morphine sulphate to determine the extent of organic dependence upon opiate medication and the amount of opiate needed to restore organic function and tone.

Tracing No. 4, taking into consideration the asthenic and exhaustion condition of the patient, shows full support to circulation with some overaction.

Tracing No. 5 was taken about an hour or so after tracing No. 4 to determine the holding power of the dosage administered, after the circulation had quieted down from the immediate action of the opiate medication. This tracing interpreted and considered together with the clinical manifestations at the time was decided to be about normal for that patient at that time.

as his opinion based on his personal deductions and his personal experience, and offered for what it may turn out to be worth.

I have for years known narcotic drug addiction to be one of the chronic physical ailments most certain of successful arrest without marked suffering or discomfort. It can be successfully treated by the intelligent clinician who is as familiar with its symptoms and clinical phenomena, and with the various physical actions and reactions of narcotic drugs upon the organs and functions of those addicted, as he should be with the symptoms and clinical phenomena of any other disease.

This is not to be done by any one special remedy or combination of remedies or by any routine method of procedure. Many drugs may be useful

ble in its clinical and pathological problems, and men of equal honesty and ability hold widely diverging beliefs.

The announcement of each new theory or belief should be taken simply for record and investigation. Much that we believe to-day we know tomorrow to be based upon misinterpretation. Much that we believed in the past to apply to and solve fundamental conditions, we found later to have been merely based upon observations of distracting incidentals or non-basic aspects and phases. What we need is some competent, disinterested, and honest effort to get together and evaluate all available material of whatever sort and from whatever source. If it were possible of accomplishment it would be of advantage to get together in open and

at different times to fulfill the indications in a given case, and their skilful selection and use is the measure of clinical ability in the handling of this disease. The belladonna group, hyoscine, cardiac stimulants, strychnine, hydrotherapy, pilocarpine, eserine, eliminants, etc., have all been used for many years and all have certain uses at some time in some cases. No one, however, who is experienced, honest, and competent will claim that any of them or any special combination of them is universally applicable to all cases of narcotic addiction as a special curative specific agent.

All are remedies of election useful in the hands of men who thoroughly know addiction-disease and are expert and proficient in the action and administration of the drugs they elect to use. The dangers and harm of the ignorant or unskilful use of these drugs, however, are daily demonstrated by those recently subjected to unskilful treatment.

I have taken out of my collection of clinical data on narcotic addiction a series of heart tracings which I have had reproduced and printed for distribution as showing graphically one example of narcotic drug action in a narcotic addict, and perhaps stimulating to further study of the clinical condition. These tracings bear on one small phase or phenomenon of addiction, but they are graphic and material and mechanical in their method of securing and they cannot distort or misrepresent. Any theory of addiction which is to survive must be capable of explaining such evidence as these tracings. They are one item of tangible evidence which must be reckoned with and there is a mass of other evidence. In the explanation of material and tangible facts lies the hope of the addict.

THE PROBLEM OF NARCOTIC ADDICTION OF TODAY.*

BY CHARLES F. STOKES, M.D.,

NEW YORK.

AN attempt to answer the query, "Whose problem is narcotic addiction?" will, I believe, sufficiently emphasize the confusion that appears to exist in regard to this grave question. Is it a sociological condition? Has it reached such proportions as to justify federal attention, or is it merely of local concern? And, further, is it not a public health matter, and, if so, has it not reached national proportions? Are we not safe in saying that addiction today menaces national security in a measure? If this is so, and I believe it is, narcotic addiction is a federal public health problem.

What part has society played in making possible existing conditions? A very direct one, and this being so, society must undo the harm done by enacting such legislation as will repair, as far as possible, the damage already incurred and prevent further contamination of the uninitiated.

Thus far we find we are dealing with a national public health problem with pronounced sociologic affiliations. By placing the responsibility at the door of the federal authorities, we are merely acknowledging that a condition exists which has passed beyond our State boundaries, one that must be corrected by federal measures that will standardize and coordinate interstate relations and activities. Our community burdens in this matter are not passed to other shoulders, any more than the community can shift its war obligations and assume an apathetic attitude.

If we are dealing with a medical problem, to which branch of medicine does it belong? Here again we find conflict and confusion. The psychiatrist says the condition is almost entirely psychic and the remedy lies in his field. The neurologist is apt to be just as emphatic in his claims, and the man of internal medicine is disposed to disregard the contentions of the other two, and appropriate the problem to himself. If there were not a measure of truth in each contention, there would be no argument. Have we not reached a point when we should be prepared to approach the problem with open minds and get at the truth? I believe we have. Those of us who have seen many cases will have little difficulty, if we have classified them all, in pointing to the psychic type, to the emotional neurologic type, and to the type in which somatic involvement apparently overshadows the other features.

While I am convinced that addiction is more widespread than is generally believed, I am satisfied to let that feature of the problem rest with the statement that it has assumed National proportions.

Let us now briefly consider the addict himself; the causes of the spread of addiction; the contami-

*Read at a meeting of the Medical Society of the County of New York, March 25, 1918.

nating agent, and its pathologic effects and the remedy.

Between three and four years ago, I took up the study of the personality of addicts at Warwick—on admission, during treatment, and at the time of discharge—and was surprised to find as the time came for them to leave the colony that I was dealing with a normal type of individual in the majority of cases. This conclusion was reached from observations of behavior, such as attitude toward others, industry, truthfulness, loyalty, and dependability. These characteristics were recorded in each case so far as possible. It was fully realized that these observations were of little scientific value, still they were suggestive, and were about all that could be accomplished with the meagre equipment at hand and lack of adequate assistance.

Through the generosity of a public spirited citizen, the services of Dr. E. W. Phillips were secured. He devoted eight months to the work, and in September, 1916, reported a study of 100 cases, which I am incorporating herein in substance as follows:

"The report is not statistical, and many of its figures are only approximate. Because of acquaintance with certain of the subjects, proper allowance for misstatement and error has been made."

"The series contained seven morphinists besides a few who had substituted heroine for morphine, and two alcoholics who had abandoned drink for drugs. Many of the older addicts started on cocaine, but there was no case of cocaine without opium habituation. Relatively cocaine seems to be unimportant."

Age.—Oldest, 48 years (a morphinist).

Youngest, 15 years.

Average age for series of 100 cases, 23 years, 7 months.

Average age for heroine addicts, 22 years, 7 months.

Average age for morphinists, 37 years, 5 months.

Nativity.—Ninety-four were born in the United States. About 50 were children of foreign-born parents.

Marriage.—Sixteen had been married, but of these 4 were morphinists.

Heredity.—Family histories as obtained from these individuals were of little value, so no effort was made to get them, beyond brief perfunctory inquiry. This brought out a history of alcoholism, however, in the immediate families of 27; 4 instances of insanity, and 4 of criminality. These figures are of value only as they have bearing on the social condition and training of the addicts.

Environment, training, and social class.—In estimating these and other variables it was found necessary to use as a standard of comparison the ordinary laborer, competent to do routine work fairly well, to hold a job, and raise a family; in other words, the low normal for American communities.

Size of families at time of admission.—Average 5 persons. They live in five rooms, with toilet usually, but no bath; they move often. The tenement and old-style flat building are the ones usually inhabited.

Neighborhood (always from the laborer's viewpoint.)—Good, 21; fair, 28; bad, 51.

Financial conditions of families.—Good (some money or property, often small tradesmen), 23; fair (prosperous, poor, decent, comfortable), 24; very poor (improvident, ignorant, dirty), 53.

Home training (estimated by speech, manner, conduct, and sometimes by history of childhood).—Good, 14; fair, 34; bad or none, 52.

Education (taking as standard the common school education that the law required before the boy is given working papers. It is assumed that a boy should be in 8-B by 15, which is a year older than the accepted school standards. Anything higher than this is called good).—Good, 9; common, 57; poor, 25; illiterate, 9.

Years retarded.—Average 1.6 years (by school standards it would be 2.6 years). Intelligence ("ordinary" equals low normal).—Good, 21; ordinary, 46; poor (stupid, dull), 20; feeble-minded, 13 (partly by Binet; partly by Terman). It happens that the incidence of feeble-mindedness in this group is unusually high; probably about 6 per cent. is normal for the type under treatment at the colony.

Previous conduct.—Incidental to the history of addiction or from some instances of public evidence, thirty admitted theft or conviction for some crime against property; 23 admitted having been in penal institutions, but this includes those who had been in protectory or parental school for truancy. Of course some concealed the fact of former incarceration.

Occupation.—Clerks (office 9, store 14), 23; mechanical and allied trades, 17; drivers and wagon helpers, 11; chauffeurs and car helpers, 4; singers, actors, musicians, entertainers, 8; no occupation, 10; odd jobs, 7; messengers, 4; laborers, 2; miscellaneous (including a few skilled workers, printers, and the like), 14.

If we seek a relation between occupation and habit we find it at once in the entertainers' group and their percentage is unduly high. It is generally held that drivers as a class are less intelligent than other workmen and their percentage is well above its corresponding one among non-habitues. Parenthetically there was not one of these 11 drivers who was even a fairly good horseman. As to the other occupations, it is to be noted that generally they do not involve much hard labor. Thirteen of these men are known to have gotten a living wholly or in part by crime.

Earning capacity.—Omitting the instance of an actor who claimed to have earned \$150 a week, and who had about him nothing to substantiate his statement, the highest weekly wage was \$35, and that not steadily. The computed average weekly wage of \$13.25 is probably a little too high.

Length of jobs.—Twenty per cent. stated that their longest jobs were less than one year in duration.

Out of work.—Fifty men said they had not been out of work one month during the past year; 12 said they had not worked at all for a year; the average unemployed time in the year preceding commitment was 3.7 months, but this includes time spent in jail.

Self-support.—Thirty-three had not supported themselves for three or more months before commitment; 18 had supported other persons, wholly or in part up to time of arrest. Average sum given to family or paid out for board was \$5.25 per week. Average cost of drug used was \$6.50 per week. These figures are probably about correct, as the ordinary addict takes all the drug he can get, and allowing \$1.50 for other than living expenses, income and outgo balance, but in many instances theft or burglary supplemented the income.

Physical condition.—When admitted to the colony was very poor generally. The average addict is 22½ years old, and for two and a half years he has taken, more or less regularly, about 60 grains of heroine a week. He has been out of work one-fourth of his time, kept very irregular hours, had eaten irregularly and not enough. There are several reasons for this last. The opiate destroys the appetite and does further damage to the digestion by causing constipation and there seems to be created an abnormal taste for sweets. Many drug addicts congregate at candy stores and besides the candy they go in for coca-cola and other caffeine drinks. Ninety per cent. of them smoke cigarettes; of these half smoke to excess (15 or more a day). The teeth, neglected in 67 cases of the series, presently decay, and there is the added disturbance of toothache and mouth infection. The average number of sound opposing molars was 3½. The average gain in weight at the colony was 20 pounds in 2 months. This is probably the average weight lost during drug use, as it is noted many skimp on food to get money for drugs. Similarly only 37 per cent. of admitted cases have good muscles; 26 per cent. fair; 37 per cent. weak and undeveloped muscles. Nose ulcers occur only in old cocaine users, as clean punched-out perforations of the triangular cartilage. There were five such cases in the series and five superficial recent ulcers said by the owners thereof to be caused by some adulterant in the heroine. There was no case of venereal disease in this series of 100 young men.

Previous cures.—"Cures" had been taken by 67, who among them had been cured 110 times. One had 5 such treatments, to relapse each time.

The average residence in the colony was 2.97 months.

The result to date is known in 37 of these 100 cases. In 5 the addict resumed the drug. The others are working and doing well.

The heroine vogue in New York dates back 7 years only. We have had a number of the original crop of heroine users. Some had used cocaine and morphine before, but none gives the history earlier than 1909, when it was introduced by the sellers as being "stronger" than morphine and easier to buy. One of its foci was in ——— neighborhood, and acquaintance with this district sheds some light on the present drug situation. It is dirty, noisy, cheap and tough. It has no park and no decent places of amusement. The houses are old and unsanitary. The people living there are largely of foreign birth; they are poor, ignorant and unskilled. Therefore, they tend to be antisocial and one can listen to their talk, on the streets or in the numerous saloons, and rarely miss the anarchistic note; still more rarely, indecency and profanity, even among children. It is not strange that boys so reared as they pass from the lax and ill-directed parental control to the equally unintelligent control of their own conduct, should tend to escape from a sense of inferiority, not by making themselves more efficient, but by the quick and easy way of narcotics. The very fact that they use the drug socially, forming organized groups that tend to enlarge and perpetuate themselves, is evidence that they are actuated by a variant of the basic human instinct to find comfort and security through cooperative effort and organization. Such are the bulk of heroine users.

There is a sprinkling of persons better bred and trained who for some reason fail adjustment in their own group and turn to the one below it. Then, too, there are the morphinists, older, more intelligent, secretive as to their habit and usually temperate in the dosage of their drug. Their relation to the heroine group is adventitious.

Back of the whole situation is the influence of those who profit by the drug traffic. These are, in ascending order, the pauperized addict who acts as seller's runner, teaches boys (and girls sometimes too) the habit, and earns a miserable living, with enough drug to get on with, till he is caught and punished; next comes the small seller, usually a negro or a bad Italian, who is protected by gang membership; next the big seller who deals with those higher up.

The cost of heroine at wholesale is about 86c. per drachm. The user pays usually \$5 for an "eighth" (a bottle containing 57 grains). Frequently it is adulterated before it reaches him. If he buys it by the "deck" he pays about double this price. Somewhere along the line this enormous profit is distributed; and it is rather significant that sellers are only occasionally caught.

From observations made of a large number of cases, prior to this report and afterward, we find that fully 90 per cent became addicted in the period of adolescence, that time when there is a dynamic urge from within which finds expression in reaching out for new experiences, novel ventures, with feeble remonstrance from the immature mechanisms of control. In order to further its ends, it is characteristic of this period to cultivate gang spirit. In the early part of the present decade heroine was heralded as the narcotic free from habit-forming tendencies. Up to that time cocaine had found favor with this group, but it has given way to heroine. What I have termed adolescent impulse, coupled with ignorance, appears to be largely accountable for the spread of heroinism. While the psychoanalysts find homosexuality an underlying factor in addiction, we have noted but few such cases. It has seemed to me more in the nature of a forceful drive that has failed to find expression in proper outlets, has failed to sublimate, a kind of hybrid intoxication impulse

that must be gratified. Frank mental disorder appears to have no direct casual relation to addiction. It is notorious that drug addicts rarely turn to alcohol; if they do, it seldom gives them what they seek and they almost invariably return to narcotics. Racial preservative impulses are largely in abeyance in narcotism, so we are scarcely justified in claiming sex urge as a cause unless there have been episodes of perversion from which the individual shrinks, and, too, this would hardly hold in the case of a gang addiction. We sometimes see distortions of racial preservative impulses among the older morphinists. There are types of individuals who shrink from pain at all levels; to them narcotics appeal strongly. In narcotism they shut out as far as possible contact with reality and drift along knowing little of the reactions of mastery and defeat. They are sheltered by the inhibition of the pain-perceiving centers and must have adequate re-educational aftercare in order that they may permanently assume a normal attitude toward society. With characteristic intemperance young heroinists are excessive in the use of narcotics and suffer accordingly.

Pipe smoking is usually begun as a group indulgence, while morphinism is solitary and secretive. Both types of habitués commonly use opium with discretion and may indulge in the narcotics for years without apparent evidence of harm. There is a small percentage in whom addiction is accidental; illness, pain, or the injudicious medicinal use of opiates may possibly have coupled them up with narcotism. These are pathetic figures.

The higher centers of control are immature in the adolescent; he chafes under home, school, and religious restrictions, if they exist, and joins with others of his type and launches forth. His standing in his gang is his greatest concern. He is confronted by heroine; his first indulgence, like his first cigar, makes him deathly sick (a defense mechanism probably due to sharp blocking off of the sympathetic with overaction of the vagus), still he is undaunted and strives to measure up to the standards of his gang and finally succeeds. To him heroine becomes the narcotic cigarette. Why do these youths not turn to alcohol? Narcotics appear to release emotional flights of a wider range, are more conveniently handled than cumbersome alcoholic containers, and, further, publicity has thrown an appealing glamour of romance about the addict. With these few suggestions as to causes of adolescent addiction, and a mention of some of the types we will pass on to a consideration of other features of the problem.

The economic loss due to the habitual use of narcotics is stupendous. Inefficiency, ill-health, idleness, and the imperative and never-ceasing crave for drugs often lead to conduct in conflict with law, and in this way a heavy burden is placed upon the community.

The pathological conditions found in morphinism are those of chronic depression as a central action, and inhibition of function as a peripheral manifestation. The depression involves various cerebral centers in the reverse order of their development; here we have a good example of the "law of dissolution." Thus, attention, self-control, and judg-

ment are lost early. Any sustained mental effort is impossible, and logical sequence in thought is lost. Dixon notes three conspicuous actions, (1) Depression of pain-perceiving centers in the cortex; (2) Depression of Auerbach's plexus (constipation); (3) Depression of medullary reflexes (respiratory sedation). Depression of the cord is less conspicuous.

Kraus insists that the peripheral action of morphine is depression of function. Inhibition of the vegetative nervous system leads to disorder of function in the ductless glands with consequent disturbances of nutrition depending naturally upon the amount and kind of narcotic used, as well as, in a measure, upon the peculiarities of the individual involved. The clinical manifestations of depression of function in the ductless glands are very striking; impairment of sex functions points to the gonads; the fat, pale, flabby morphinist is suggestive of athyroidism. In one series of heroine addicts observed by me, 70 per cent. had grossly defective, notched, and rigid teeth resembling those seen in parathyroid tetany, probably due to deficiency in calcium from parathyroid involvement.

Tolerance.—The acquired tolerance to morphine is not clearly understood. Some contend that the body oxidizes the excess; in those not addicted, 40 per cent. of the morphine introduced hypodermatically is eliminated by the stomach and most of the balance by the intestine. Other avenues of elimination are the tears, saliva, breath, and sweat. After habituation has been established and the usual dosage has been taken, no morphine can be found in the intestinal tract unless an excessive amount has been administered, when the excess is eliminated in this way. If an addicted animal is killed after the usual dosage, no morphine can be found in its tissues. *It has been suggested that morphine is split up into inert bodies by a ferment-like action, which seems probable.* As central depression and peripheral inhibition of function are slow down processes, hypoactivity, permanent structural changes do not follow, hence laboratory investigations are more or less fruitless. This is in marked contrast to the conditions in chronic alcoholism in which we have hyperactivity and a biochemical defense of sclerosis and steatosis. The question of immunity and antibodies, Wells (1918) dismisses as follows: Immune substances cannot be produced against ptomaines, and for that matter, against the vegetable alkaloids, or against chemical bodies of known constitution." It is important to bear in mind that tolerance ceases after a day or two, and that narcotism can be induced by relatively small doses at this time. Death has followed an addiction dosage after a relatively brief period of abstinence.

Abstinence Symptoms.—In narcotic addiction there are varying degrees of long-standing disturbances of metabolism and proportional nutritional damage notably in the nervous system. The intake of food is cut down as a rule, digestion is retarded, and assimilation is sluggish, all of which have a direct causal relation to the impoverishment of cell protoplasm found in these cases. The depression of certain cells in the cortex, in the medulla, and in the vegetative nervous system as a selective narcotic effect, probably still further adds to the nutri-

tive disturbances, and may, in a measure, account for the acute hyperactivity and subsequent exhaustion of these cells so characteristic of withdrawal conditions. Prolonged cortical depression materially disturbs development at psychic levels, probably largely accounts for the abnormal attitude toward reality, and is, as noted, very suggestive of the proper line of procedure to be followed in the after care.

The effects of opium wear off in about twelve hours; usually, however, in six or seven hours restlessness, anxiety, and depression supervene, in other words, beginning abstinence symptoms appear. In accordance with pharmacological and biological law, sharp withdrawal of drugs that depress function induces backsway or counterfeit stimulation, the hyperactivity of release. This is well shown in morphinism. Hyperactivity at psychic levels is overshadowed for a time by emotional crises in the vegetative nervous system. Release of the respiratory center is manifested by respiratory disturbances of excitation such as sneezing, gaping, rapid respiration, and the like. We see evidence of sensory release in the cord in twitchings, pain, and cramps. The most conspicuous symptomatology, however, appears to be due to the sharp output of adrenin, and the subsequent activation of the thyroid and other organs, there is acute excitation of sex functions, as shown by pollutions and erotism. The clinical picture is perfect,—wide pupils, pallor, rapid and irregular respiration, and other respiratory disturbances, rapid heart action often running on to exhaustion, inhibition, and blanching of the gastrointestinal tract. The facies in severe cases is that of profound fear. Biedl and others have called attention to the rise of temperature induced by adrenin.

Canon has observed preganglionic fibers that go direct to the adrenals; this distribution probably accounts for the prompt output of adrenin in response to impulses from the brain. Adrenin in turn activates the brain, the thyroid, the liver with the release of glycogen, and inhibits the vagus. Crile has shown that morphine checks the output of adrenin; clinically, a moderate dose will give immediate relief in abstinence symptoms. Deeply narcotized animals fail to react to toxins.

While intestinal intoxication may be a factor in this condition, in my opinion, it is one of secondary importance. Psychic manifestations play an important part, without question, still they, too, are subordinate to the disturbances in the vegetative nervous system. In infants born of addicted mothers, abstinence symptoms cause death usually on the third day after birth, sometimes earlier, unless relief is given. According to Schaeffer, the adrenals in the human fetus are unusually large. Communication with the maternal intestine ends at birth, and as no other source of intestinal intoxication exists in the child at this time, the intake of toxic bodies from this source must cease abruptly. If abstinence symptoms were due to this cause, under the conditions noted, we should hardly expect to find the symptoms increasing in severity and of such gravity as to cause death on the third day.

The brain at birth is probably incapable of responding to psychic stimuli except in a primitive way, so that it would seem to me hardly credible

that the fatal manifestations seen in these cases should have a psychic basis.

It has been demonstrated biologically that on the withdrawal of agents that induce hyperactivity we have depression. In like manner, on the withdrawal of substances that induce depression of function, the pendulum swings to hyperactivity unless stopped. The extent of the backsway depends largely upon the duration and the degree of the depression. It is significant that deep narcotism interferes with the action of toxins. Immunity cannot be induced by alkaloids and tolerance ceases on the withdrawal of the depressing agent.

Addicts are held in addiction largely through fear. Prolonged indulgence usually fails to give them pleasurable sensations, still they must go on in order to avert the crisis of withdrawal in which the backsway of the pendulum from chronic depression of the pain-perceiving centers brings about a sharp excitation. Oftentimes we find that addiction is basically largely an expression of inability to confront pain in its broadest psychological sense. This type of personality coupled with addiction adds to the dread of withdrawal and favors the probability of relapse.

After the subsidence of the acute abstinence symptoms we have a period of nervous irritability and hypersuggestibility which demands special consideration. Physical equilibrium is readily established while stability in the nervous system is a slower process. I am of the opinion that intestinal intoxication, if it exists at all, is of minor importance, and that psychic manifestations are overshadowed by reactions at a lower level. As noted at the outset the pathology invades the territory of the neurologist, the psychiatrist, and the internist. The picture is a composite one; at first glance the nutritional damage excites attention.

Preventive Measures.—It was realized fully three years ago that we were hopelessly involved in a vicious circle in returning men to the city from Warwick under conditions then existing, and for that matter, still existing. They were confronted by heroine sellers, old associates, addicted women, and many relapsed. The crowd attitude is irresistible in youth, and we found ourselves engaged in the absurd endeavor of trying to "cure" adolescence.

It became evident that in order to accomplish anything of account in this work heroine must be abolished. I took the matter up with the Surgeons General of the Army, Navy, and Public Health Service, whereupon the public health service removed heroine from its supply table and from all its institutions. Not only should heroine be abolished, but, in my opinion, the Federal Government should have control of opium and all its narcotic derivatives, and should be responsible as well for their distribution for use in medicine. Should effective restrictive measures be instituted, we should provide adequate hospital facilities at the same time. It is extremely important that ample provision be made for the treatment of women.

It is desirable that all sanatoriums in which addicts are treated should be under State supervision, and that physicians engaged in the care of these cases be licensed much as examiners in lunacy are enrolled, provided they are properly qualified.

morally and professionally. An educational drive should be launched in order that addicts may learn their true condition, what they may reasonably expect from treatment, and, too, what they may expect in case they continue in addiction. In this connection we might ask, what effect is prolonged addiction in the period of adolescence going to have upon the development of future character? What effect will the deficiencies in calcium have upon the growing bony frame? A radiographic study of addicts might be profitable in this connection. There has been entirely too much mystery and glamor thrown about this problem. We should stimulate the right kind of public interest in this matter, and win the support of an enlightened press.

We have been much interested in addiction as a mass problem especially in connection with the loss of man-power in its relations to the war. Attention is called to an article on this subject in the *Journal of the American Medical Association* of March 16, 1918. We have prepared an educational pamphlet for circulation among the military forces with the idea of averting contamination in this way.

Treatment.—We believe that treatment to be effective should be carried on in three stages: First, withdrawal of the drug; second, reeducational measures; third, after-care and follow-up. Of course, modifications should be made to meet individual conditions, still, the general principle should be adhered to. There were exceptional opportunities at Warwick for observing convalescence after various methods of treatment; after some, it was unduly prolonged; after others, serious and apparently permanent injury was noted. Two cases of unilateral paralysis of the third nerve, traced for three years, with no improvement, and functional disuse with much disfigurement, followed a popular method. After another method, mydriasis and flushing persisted for a year and a half, when the patient was lost sight of. There were other cases that we are unable to trace.

Substituting one powerful alkaloid for another, in massive doses, in a purely empirical way, never appealed to me. Our early cases were isolated as far as possible, and were given active cathartics, and as much encouragement as circumstances permitted while the drug was rapidly removed in say three or more days. They were given warm baths, hypnotics, and later, bitter tonics. They suffered considerably and convalescence was frequently slow. Here and there one did fairly well. The difficulties of attempting to put a clinical problem on a scientific basis, the findings of which cannot be confirmed in the laboratory, was appreciated at the outset; in this undertaking, presumably one man's opinion is as good as another's; it is on a par with trying accurately to record a temperature without a clinical thermometer. My conception of the pathology of addiction has been outlined briefly. In planning the treatment I have followed the indications of this pathology.

The indications in the first stage are to hold back the output of adrenin, and so to stimulate the vagus that it may effectively balance the overaction of the sympathetic. Ductless gland products were found to be too slow in action even though they were reputed to be active autonomic

stimulants. On searching the literature, it was found that Biedl, Falta, and Hess and Eppinger had carefully investigated the actions of pilocarpine and eserine and found them powerful vagus stimulants. British and American literature is unsatisfactory on these drugs.

The plan of treatment employed by us is to isolate the patient, as far as possible in accordance with the Weir Mitchell plan; to hold back adrenin with a single dose of morphine, gr. $\frac{1}{4}$. A half hour later, to give pilocarpine, gr. $\frac{1}{10}$ to $\frac{1}{15}$ (a half to a third of the usual medicinal dose). Later the dose drops to gr. $\frac{1}{20}$ or $\frac{1}{25}$. Eserine gr. $\frac{1}{60}$ is given at the same time as an initial dose; later half this amount is given. Eserine is discontinued when the bowels move freely. As the action of these drugs ceases in about three hours, they should be given every two and a half or three hours. This medication is continued for two or three days; should the interval be lengthened beyond three hours at any time, the patient will manifest withdrawal symptoms. Occasionally a single dose will admirably quiet a restless patient after these drugs have been discontinued. The narcotic can be taken away abruptly, without distress. The patients doze most of the time for the first two days. If they are restless one or two doses of morphine sulphate gr. $\frac{1}{16}$ to $\frac{1}{8}$ will quiet them satisfactorily. As a rule patients cannot tell when the narcotic is discontinued; they have no craving. In order that we may get these results, the drugs should be fresh and active, and the treatment should be carried on with precision and intelligence, which can only be accomplished through good nursing. I have seen no untoward symptoms. The heart action should be slowed down from 6 to 8 beats. This is a good indication as to the proper dosage. The saliva should be expectorated, otherwise antiperistalsis will be induced. The patients are often ravenously hungry by the end of the first twenty-four hours. After the third day we may give luminal, elixir of veronal, or sodium bromide for the wakefulness. Bitter tonics with alkalies are often indicated; calcium may be given in a single dose each night so as not to upset the digestion. The diet should be easily digested and nutritious. We give fluids the first evening. Rest, quiet, and nutrition are our sheet anchors at this time. By the fourth day the picture has changed to one of nervous exhaustion, nervous irritability, and marked suggestibility. During the period of medication the pilocarpine and eserine have a very striking tranquilizing effect. If there is any virtue in elimination, the sweating, salivation, and purgation should accomplish it. We use simple measures, such as bathing, light massage, and occasionally the sinusoidal current, after the vagus stimulants have been discontinued. It is interesting to note that fright and anger will throw the patients into withdrawal symptoms at once. It is wise to discontinue medication as early as possible, for these types are inclined to seek props and pick-me-ups on the slightest pretext.

The second stage. An exhaustive history must be taken in order that we may be prepared to undertake reconstruction of the personality, effectively. Our plan is one of reeducation and the development of will, judgment, and a proper attitude

toward reality. The methods of Dejerine and Gauckler are excellent. They are based upon the principle of disclosing to the patient his true condition from all angles, and stimulating his judgment, not by suggestion, but rather by indirect methods.

The third stage. Patients should now be ready for their try-out in the community. Their routine should be carefully mapped out so that they do not become mentally or physically fatigued. They should report at least once a week for some months. When this plan of treatment is carried out the results are satisfactory, unless we are dealing with cases in which addiction is adventitious. Convalescence begins early and progresses rapidly. Now and then we find a case in which there is no intention of relinquishing the use of narcotics. We all see cases in which narcotism should be continued for humane reasons.

Treatment in the first stage should be regarded as merely preliminary. We believe we are safe in saying that unless treatment can be carried through the second and third stages, it might better not be undertaken, in the majority of cases. In our private work we aim to take the patients off their drug at a suitable place in the city; to give the treatment in the second stage out of town. The after-care and the follow-up are attended to in the city at a third point conveniently located and freed as far as possible of suggestive associations. The advantages of such a plan are obvious. Too much emphasis cannot be put upon the importance of having control of our patients while they are under treatment, and this can be accomplished only in suitably equipped institutions. These patients almost invariably overestimate their mental and physical resources, and they are apt to chafe under restrictions of any sort. Their care calls for nicety of judgment, great tact, and abiding patience.

I am indebted to Dr. George W. Crile, of Cleveland, and to Drs. Charles H. Mayo and E. C. Kendall of Rochester, Minn., for their assistance in working out the pathology and treatment.

50 EAST FORTY-SECOND STREET.

CELLULAR CHANGES IN VARIOUS FORMS OF ACUTE LEPTOMENINGITIS.

By G. B. HASSIN, M.D.,

CHICAGO.

ATTENDING NEUROLOGIST, COOK COUNTY HOSPITAL.

THE various types of acute leptomeningitis—purulent, pneumococcal, tuberculous, and epidemic cerebrospinal—can be clinically more or less successfully diagnosed. The differential clinical diagnosis is based not so much on the symptoms and course of the disease, as on the lumbar puncture findings. However, a differential *anatomopathological* diagnosis at least of some of the forms of acute meningitis is exceedingly difficult, and it must be conceded that so far comparatively little, if any, effort has been made for the purpose of establishing or determining what changes in the meninges obtain in any given form of acute meningitis. In fact, a pathological diagnosis of the latter is not considered

*From the Pathological Laboratory of Cook County Hospital.

possible with the probable exception of typical cases of the purulent and tuberculous varieties. It is also a fact that, while the literature relative to the latter two forms, and especially the tuberculous meningitis is enormous, there is very little written about the other forms. Therefore, I wish to report briefly my findings of cellular changes in eleven cases of acute meningitis, of which two were purulent, four tuberculous, three epidemic cerebrospinal, and two pneumococcal.

Purulent Meningitis.—The two cases of this form were from patients who developed an acute meningitis secondary to an otitis media. The meninges, *i.e.* the pia-arachnoid, macroscopically were greatly infiltrated with pus and appeared much thickened. Microscopically, there were pronounced vascular and cellular changes. The former were especially in evidence in the inner layer of the pia immediately adjacent to the brain tissue. The vessels were greatly distended, hyperemic, and always excessively infiltrated. The infiltration was mainly limited to the dilated perivascular spaces of the adventitia and consisted of various hema-

FIG. 1.—Cellular findings in purulent meningitis. 1-5, macrophages; 6-9, polyblasts; 10-13, plasma cells; No. 13 is vacuolated; 14, fibroblast; 15-16, Gitter cells; 17-19, pus cells.

togenous elements, principally *plasma cells* and *polyblasts*. The same elements could be found in very large numbers in the distended meshes of the pia connective tissue, whose collagenous fibers were much separated. In the meshes, besides the plasma cells and the polyblasts there were present also numerous *macrophages* and *fat-granule bodies*, also known as "Gitter cells" (Fig. 1). The plasma cells appeared quite typical—showed a large cell body with a dislocated or rarely centrally located nucleus surrounded by a distinct membrane. The inner surface of the latter was covered with densely stained particles of chromatin in the form of spokes. Some of the plasma cells hardly showed any cytoplasm, while in some it was vacuolated, or contained more than one nucleus, and some plasma cells appeared of an enormous size, as giant plasma cells. The polyblasts showed as mononuclear leucocytes, sometimes round in shape, but as a rule their cytoplasm was irregular in shape, pale, and often vacuolated. Their nucleus was biscuit- or kidney-shaped, pale, and its chromatin was in the form of a thin network. Their size was like that of the plasma cells, very large.

Much more numerous than the polyblasts were other mononuclear elements, namely the *macrophages* (Fig. 1). These were much larger in size than the two previous forms and consisted of a great number of large vacuoles packed with pus cells, erythrocytes, pigment, fat globules, etc. In alcohol specimens the macrophages frequently appeared empty, showing an irregularity in shape, flattened, mostly eccentrically located nucleus. The macrophages were numerous in those areas that contained few pus cells.

The *fat-granule bodies* or "Gitter cells" were found in large numbers around the blood vessels as well as in the meshes of the pia. They were quite typical—honeycombed in appearance, round or oval in shape, consisting of an enormous amount of minute vacuoles packed, in suitably stained (scarlet red, for instance) specimens, with fat-like or lipid substances. In alcohol specimens the vacuoles appeared empty, and the nucleus was almost always excentrically located and frequently much flattened.

Besides these four types of cellular elements there could be distinctly seen in the meshes *fibroblasts* (Fig. 1). These contained an oblong large pale nucleus surrounded by a spindle-shaped cytoplasm emitting processes from its opposite poles. Like the macrophages, they frequently contained pigment, fat, etc., and like the rest of the infiltration cells they were unusually well developed and often vacuolated.

Some areas of the inflamed pia showed none of the above-described cellular changes, but were covered by an enormous amount of *pus cells*, mainly *polynuclear* elements. In such areas the latter formed the principal mass of the infiltration cells and actually dominated the field. Frequently they were packed with pyogenous microbes, and always could be seen in larger or smaller amounts even in those areas where some of the former elements were predominating. Therefore, the presence of *pus cells* mostly in the form of polynuclear elements must be considered quite typical for the purulent variety of acute meningitis. Here, namely, it is possible to demonstrate dense foci of pus cells, without any of the previously mentioned cells being present among them. Occasionally a lonely macrophage can be encountered in the pus focus, but where the pus cells are less numerous, where the areas are free from pus cells, there are to be found large numbers of plasma cells and macrophages, the latter frequently packed with pus cells. As the plasma cells are nothing but modified lymphocytes, we may say that lymphocytes, like the macrophages, are to be met with only in these areas that are poor in pus cells, but where the latter predominate, the lymphocytes are totally lacking.

The above cellular changes are not equally represented all over the changed pia. The inner layer of the latter is usually very vascular, rich in vessels, and is therefore called by Cerletti's *zona vasalis*. The middle layer showed a great wealth of fibroblasts, while the macrophages and "Gitter cells" were very numerous in the *external* portions of the pia. Plasma cells were equally well represented in every layer and were very numerous around the vessels. Such peculiarities in the distribution of the pia changes in meningitis were described by

Cerletti in a pernicious anemia case from which the purulent variety differs by the presence of a great number of pus cells. The occurrence of the latter in the form of foci of diffuse infiltrations of the pia meshes can thus be looked upon as typical for purulent meningitis where a microscopical diagnosis should not afford any difficulties.

Tuberculous Meningitis.—Equally typical are the microscopical findings in tuberculous meningitis which was studied in four cases, all from children. In all these cases the pia of the base, around the chiasma, peduncular region, pons, and medulla, macroscopically appeared thickened, as if infiltrated with pus. Microscopically, in these areas, there could always be seen an enormous amount of vessels with greatly thickened proliferated and hypertrophied walls (Fig. 3). The latter were often merged with the neighboring areas, forming sometimes one uninterrupted area in which it was commonly hard to make out which of the infiltrated places belonged to the vessels and which to the pia. With the lower power the specimens appeared very badly stained, and but with great difficulty cells could be discerned containing a pale homogeneous nucleus that was either totally devoid of chromatin or contained one or two minute granules surrounded by a very small rim of protoplasm (Fig.

FIG. 2.—Some cellular findings in tuberculous meningitis. 1, macrophage; 2-3, degenerated plasma cells surrounding amyloid bodies; 4-6, plasma cells as originally described by Unna; evidently degenerated; 7-9, "rod" cells ("Stäbchenzellen").

2). Some of the cells appeared as naked nuclei, *i.e.* without any protoplasm whatever, and could be found also within the blood vessels. Some of these cells showed small processes, pseudopodia, when they much resembled fibroblasts, which here are quite numerous. In the external layers of adventitia the same pale homogeneous nuclei could be found with a densely stained cytoplasm, the cell bodies assuming quadrangular or irregular shapes, usually very small in size. In Van Gieson specimens these cells resembled plasma cells crowding in enormous numbers the meshes of the vessel walls and of the adjacent pia. Nearer to the brain tissue they still more resembled plasma cells, but were not altogether typical. Their cytoplasm stained much denser than the nucleus which, as I said, always appeared pale and without the characteristic arrangement of the chromatin globules. Such plasma cells as found here much resembled those originally described and depicted by Unna² (Fig. 2). Sometimes they formed large round foci, resembling tubercles surrounding amyloid bodies, pressing on the vessels against their walls and frequently causing narrowing of their lumen. These cells are also found in large masses in the pia meshes, which besides are packed with fragments

of various cells and with an amorphous unstainable necrotic mass. Any detailed or adequate description of the amorphous mass is hardly possible as various stains tried (hematoxylin-eosin, toluidin-blue, Van Gieson, methyl-blue-eosin, etc.) did not furnish any satisfactory data regarding its structure. It covers the entire visual field and is usually described as a cheesy or tuberculous mass (Ranke,¹ Hektoen,¹ Wolff²). Aside from the plasma cells, the fibroblasts, and the amorphous mass, the microscopical examination also reveals peculiar vascular changes. The vessels are much infiltrated with these cells; their lumen is, as a rule, preserved, though sometimes, but very seldom, obliterated by thrombus. The intima is in the form of large swollen endothelial cells with distinct processes and a homogeneous pale nucleus containing a nucleolus. The endothelial cell bodies often thin out into processes which anastomose with similarly thinned processes of the neighboring cells, forming a row resembling a chain. In some specimens the intima is separated, as if torn away from the elastic membrane, a few blood cells filling sometimes the space between the intima and the elastic membrane. In larger vessels I could find in these spaces also polyblasts, plasma cells, macrophages, and "Gitter cells" (fat-granule bodies), but not so frequently and not in such amounts as did Hektoen, Ranke, or Diamond.³ Macrophages are unusually numerous in Ranke's microphotograms, as well as in Diamond's specimens, which I had the opportunity of studying. Diamond described them as subendothelial—epithelioid cells; while Hektoen calls them giant cells. The typical vascular changes consisted of a tremendous development of connective tissue around the vessels which looked like a veritable scar inclosing various infiltration cells. These were almost exclusively plasma cells in the form pictured above and which evidently were degenerated. There could also be seen a few polyblasts, macrophages, and so-called "rod" cells ("Stäbchenzellen"), the latter only in specimens stained with toluidin-blue. Polynuclear or pus cells, so numerous in the purulent variety of acute meningitis, were here totally absent. The polynuclears were found by Ranke, Gehry,¹ and Diamond, but in very few numbers, while Rhein⁴ claims he could see them quite frequently. In the great scarcity of the polynuclear elements tuberculous meningitis differs, in my opinion, from the purulent form where, as I said, they are unusually frequent. This fact, in connection with the peculiar appearance of the visual field which showed an abundance of vessels with greatly hypertrophied and infiltrated walls (periarteritis or arteritis of some authors), is I believe quite characteristic for tuberculous meningitis and should be of great help in the differential diagnosis. This can be gathered from the following somewhat unusual case, where a differential diagnosis from purulent meningitis was very difficult:

A child, six weeks old, was brought to the pediatric service of Cook County Hospital, Oct. 2, 1917, in a comatose state. Three weeks previously the child began vomiting, had diarrhea and repeated convulsions. Since birth the patient had been fed on a mixture of milk and water (one ounce of milk and two ounces of water) and condensed milk. The family and previous histories were negative.

The examination showed an extremely emaciated infant whose entire body and extremities were cold. The

breathing was of a Cheyne-Stokes type, cyanosis was absent, the fingers and lips had a good color. The heart sounds were distinct and of normal rate; so was the pulse, though very feeble. The eyes were closed, turned with the head to the left, and showed a nystagmus. The pupils were dilated, unequal; the left was larger than the right. Brudzinski's sign was positive. The spinal puncture gave an intensely yellow spinal fluid under increased pressure with 300 to 325 cells, mostly mononuclears (80 per cent.) per cu. mm. Death followed a week after the child's admission to the hospital.

The postmortem, as the records show, revealed a basilar tuberculous leptomeningitis, caseous tuberculous ependymitis, a marked dilatation of the ventricles of the brain, hyperemia and edema of the leptomeninges. The examination of the viscera and of the spinal cord was not made because of limitations placed upon the consent to an autopsy examination.

Further examination of the brain showed that the meninges, especially around the fossa sylvii, were covered with tubercles and appeared greatly hyperemic and thickened. The inner surface of the pia, the lateral, the third, and the fourth ventricles were filled with a generous layer of cheesy soft pus-looking mass that was somewhat loosely attached to the pia and also invaded, in many places, the parenchyma of the brain tissue proper. The latter was greatly edematous, soft, and glassy looking, the convolutions were somewhat broadened, the sulci narrowed. The general impression was as if the entire mass of the brain was bathed in or infiltrated with pus.

The microscopic examination of the cheesy mass showed a great number of vessels with narrowed lumina and enormously thickened and infiltrated adventitia. The infiltrated vessels merged with the surrounding tissues which, like the vessel walls, were packed with a great number of various cell elements. Some of these appeared as densely stained homogeneous cell bodies, some were vacuolated cells, or were broken up in granules, in unstainable fragments of various cells as lymphocytes, red cells, etc. Some appeared as "gitter-cells" and all these cell masses filled up the vessel walls and the surrounding tissues to such an extent that the vessels could be discerned only with great difficulty. The infiltration mass appeared as necrotic tissue that stained very badly. The brain tissue adjacent to the necrotic cheesy mass showed an enormous proliferation of glia tissue cells which showed an abundance of protoplasm and of cellular processes (Deiter's cells). The ganglion cells were uniformly changed. They all appeared vacuolated with densely stained tortuous processes, a pycnotic, *i.e.*, intensely stained nucleus, and a nucleolus. Many portions of the brain showed a distinct glia reticulum covered with an enormous amount of glia nuclei which frequently formed foci. The brain vessels were greatly increased in number, with infiltrated and proliferated adventitial layers. The changes described in the glia and parenchyma were equally pronounced in the pons and medulla. The proper pathological diagnosis of this case would be a meningoencephalitis of tuberculosis nature as evidenced by the presence of the tubercles as well as by the microscopical findings. The involvement of the brain tissue in this case was exceptionally severe, while in the previous cases of this series the brain tissue was very little involved. In other words, the meningeal infiltration as a rule did not invade the brain tissue proper which, however, sometimes showed cellular vascular infiltrations which almost exclusively consisted of plasma cells.

In *epidemic cerebrospinal meningitis* the pia was, as in the previous two forms, greatly infiltrated with plasma cells, lymphocytes, polyblasts, "gitter cells," and also polynuclear leucocytes. The infiltration of the vessels was very intense and consisted in many instances of plasma cells only. These cells also predominated among the infiltration elements of the pia, where they frequently showed as pure cultures, especially in its inner zone, that is, the one adjacent to the brain. Polynuclears and lymphocytes were also to be seen, especially in the middle

and external portions of the pia, while vessels were equally numerous in all the pia layers and often showed an enormously proliferated adventitia surrounding the vascular lumen in the form of a muff. A few plasma cells were also to be found in the marginal glia of the brain tissue, but none in its remote portions. Aside from the plasma cells, polyblasts, lymphocytes, and polynuclears, there were also present numerous rod-like cells ("Stäbchenzellen"), macrophags, and fibroblasts. The rod cells could be seen only on specimens stained with toluidin-blue or similar stains. They showed, as their name indicates, as small rods with dull edges, containing an oblong nucleus filled with numerous small chromatin particles. They are as Cerletti positively demonstrated, mostly adventitial cells and do not show in specimens stained, for instance, with methyl-blue-eosin when they appear as nuclei of the adventitial cells. The macrophags and "gitter cells" were very numerous in those portions of the infiltrated pia that were comparatively poor in lymphocytes and polynuclears, while in densely infiltrated areas they were almost entirely absent. Scattered among the various elements in the pia there could be discerned large pale nuclei with few chromatin granules, invested with a distinct membrane and a very faint, hardly visible rim of protoplasm. In some of these nuclei, after a long diligent search, there could be discerned a larger amount of cytoplasm breaking up in processes emanating from the opposing poles, and occasionally showing vacuoles. These cells were most probably fibroblasts which, though quite numerous, were overshadowed by other types of infiltrating elements which, as I said, were mainly plasma cells, lymphocytes, and polymorphonuclear leucocytes. The presence of the latter distinguishes the epidemic form of meningitis from the tuberculous variety where they are usually absent.

In *pneumococcal meningitis* the pia shows the same elements as in the previous forms—plasma cells, pus cells in the form of polynuclear leucocytes, fibroblasts, macrophags, "gitter cells," and comparatively few lymphocytes. In osmic acid specimens they show an enormous number of dark granules, sometimes big enough to fill the entire cell body. Especially numerous are the pus cells, macrophags, and "gitter cells." In some specimens the latter two cell varieties predominate, in others the pus cells. Some macrophags very much resemble the so-called myelophags which are gliogenous elements found in secondary degeneration of nerve fibers. The function of the myelophags, as was discussed by me elsewhere,¹ is to break up the fragments of damaged nerve tissue (myelin and axone) into smaller particles, convert them into fat-like, so-called lipid, substances and deliver them to other gliogenous formations known as "gitter cells." Their function is partly phagocytic, partly that of sweepers or cleaners. This same function is rendered by the macrophags in acute meningitis where they clean up the invaded, polluted, so to speak, meninges from the various débris (pus cells, degenerated lymphocytes, pigment, fat, etc.), converting them into lipid substances and storing them up in the "gitter cells." The latter are here perfectly similar to those found in the pathological glia tissue. Like in the purulent and cerebrospinal

varieties of acute meningitis the macrophags and "gitter cells" are to be found principally in those parts of the pia which are comparatively little infiltrated. They are frequently found together with plasma cells which are of enormous size, especially near the blood vessels. The latter are, as in any other form of meningitis, greatly infiltrated and show within their lumen the same plasma cells as well as macrophags and lymphocytes. Some vessels are densely surrounded by large fibroblasts and "rod" cells, and their adventitial spaces are filled with a great number of "gitter cells" loaded with fat. The fibroblasts are always very large in size, spindle shaped, with a chromatin-rich nucleus, and are often packed with pigment.

The microscopical findings in pneumococcal meningitis can be summed up as follows: Some areas are densely infiltrated with pus cells without any other element being present; other places show hardly any pus, but a great number of plasma cells, lymphocytes, and especially macrophags loaded with pus cells, lymphocytes, etc. Near the brain tissue the pia is rich in macrophags and very poor in pus

latter there can be found areas exclusively covered by plasma cells and macrophags and totally devoid of pus cells, which is not the case with the purulent form where pus cells can always be demonstrated. In the cerebrospinal epidemic type the polynuclear elements are as frequent as the lymphocytes, but again combined with the above mentioned types of infiltration cells. The polynuclear leucocytes are comparatively rare in tuberculous meningitis. Their presence, therefore, alongside the lymphocytes may speak for the cerebrospinal epidemic variety of acute meningitis.

From this brief sketch it can be seen that there exists some basis for a differential diagnosis of acute meningitis, which can be made from the presence of various types of infiltration cells, provided suitable staining methods are used. Of these methods the best ones proved to be for this purpose: Van Gieson's, hematoxylin-eosin and methyl-green-pyronin, as well as toluidin-blue and Alzheimer's method V (methyl-blue-eosin).

A PLEA FOR THE USE OF POTASSIUM NITRATE IN THE TREATMENT OF CANCER

BY EDWARD PERCY ROBINSON, M.D.,

NEW YORK.

IN a previous article which appeared in the *MEDICAL RECORD* of September 1, 1917, under the caption, "An Hypothesis Regarding the Physiochemical Nature of Cancer," the writer suggested the timeliness of boldly questioning the efficacy of surgery in the treatment of carcinoma, and remarked, "Good reason exists for believing that in this particular field the surgeon, having been weighed in the balance and found wanting, should step aside to give the hitherto discredited physician another chance to propose measures of relief." He still feels, from what is about to follow, that this suggestion will bear reiteration. However, before giving his reasons why the physician should wrest the

FIG. 3.—Tuberculous meningitis. The pia shows six infiltrated vessels and other changes explained in the text.

cells, while the middle portion of the pia shows just the opposite. In no other form of meningitis is the role of the macrophags so apparent; in no other form are they so numerous as in the pneumococcal type. The brain substance proper shows, as in the previous two varieties, some vascular changes, as perivascular infiltration and occasionally some ganglion-cell changes which will not be described here.

These are, in brief, the findings of cellular changes in the four main varieties of acute meningitis. In all of them plasma cells, macrophags, and lymphocytes are constantly to be found. The pus cells, when present, alone or in combination with these elements, may speak either for a purulent or a pneumococcal meningitis, and a differential diagnosis then may be very difficult, though in purulent meningitis the pia infiltration with pus is much more pronounced and the fat granule bodies ("gitter cells") are also more numerous than in the pneumococcal variety. On the other hand, in the

cancer patient from the surgeon's knife, a brief review of the salient features set forth in the original hypothesis will be pertinent to the subject, of which the following are abstracts:

The initiative stage of cancer is that of hyperemia, occurring in any part of the body, and caused either by traumatism or toxic products from bacteria or chemical substances. The next step is the passing of the hyperemia into an inflammation. As inflammation is the first step in physiological repair this function becomes operative and is manifested by the process of proliferation of the cells involved. In the normal processes of repair the cell division is perfect and uninterrupted, and proliferation and growth continue onward until healing is completed. But if there exists in the blood a condition, which might have the effect of stimulus, a formative stimulus, as it has been conjectured, the physiological processes of cell division become disturbed and irregular, the cytoplasm no longer dividing with the nucleus, the result is a giant cell. "A single organism can grow and develop only up to a certain point, limited by its degree of specialization. That further progress may be made, the individual life must cease and give place to a successor." If one is to believe this fundamental truth as expounded by Prof. F. H. Pike, it is evident that a giant cell has lost its degree of specialization and is incapable of further proliferation and growth and must die without progeny.

Statistics were given to show that those organs having a large blood supply, or those physiologically active in metabolism, constructive or destructive, are more liable to be affected with cancer than those not so highly vascularized. The greater proliferative capacity of the female as compared with that of the male, is thought to be the cause of the higher percentage of cancer in women than in men.

Excluding all other causes, traumatic or bacterial, and considering the chemical influence solely, it was assumed in the hypothesis that the active and predominant cause of cancer lies in the excessive use of sodium chloride or common table salt. That there might exist in certain families idiosyncrasy for the use of sodium salt led the writer to infer that the prevalence of cancer in such families was due purely to this idiosyncrasy, and not to any particular hereditary tendencies to cancer capable of transmission from parent to offspring.

The writer stated that traumatism was an inciting factor, yet not the direct cause of cancer; in other words it serves merely to kindle the hyperemia. In so far as proliferation is the first step in the repair of tissue, it might be reasonable to assume that malignancy might be instituted in the cell at the time that mitosis was taking place, and, instead of the division being physiological and regular, the cytoplasm did not divide with the nucleus but produced a degenerate cell. In the MEDICAL RECORD of February 9, 1918, page 258, it is noted that "MacCarthy believed the disease to begin in the waiting or repair cells," and Dr. Charles H. Mayo remarks that, "We thus saw how the stimulation of continued traumatism might stimulate to activity such repair cells when lack of control, differentiation, and migratory hyperplasia would place them within the cancer classification." Mayo is

further reported as saying. "Nearly one-third of the cancers that affected man were found in the stomach where acidity was constant and high. The duodenum which by right of continuity of tissue, close association with an opportunity for grafting, and apparently far more commonly affected by ulceration than the stomach, was almost never affected with cancer, which, however, spread into all other tissues around it when developed from gastric cancer."

The importance then of the constancy of acidity in cancer should be borne in mind as being of utmost importance with its relation to sodium chloride in the plasma and tissues.

Can the question be properly raised, "Is cancer a distinct entity?" In the light which pathology has thrown upon the different phases of inflammation, might not cancer be nothing more than an exaggerated phase of an original inflammation, possessing no other characteristics than the peculiarity of the presence of atypical cells in the inflamed tissues? What is there to lead one to believe otherwise? Does not cancer start with an inflammation, and has anyone ever seen a cancer in which inflammation was not present? The mere fact that cell division is interfered with, in the process of an inflammation, cannot make that condition a distinct and separate pathological state while the original cause of the inflammation still exists. It seems not impertinent to ask why cancers do not develop in uninflamed tissues, but are prone to develop in old inflammation. It seems to the writer that without inflammation there can be no cancer. (In this case the deduction is that cancer is an inflammation of a malignant type.)

The word cancer is derived from the Latin *cancer*, a crab, as carcinoma from the Greek *karkinos*, which also means a crab. Both of these different speaking nations evidently recognized in this disease the close resemblance to this particular crustacean and so named it accordingly. There seems no special reason why the crab should have received this distinction unless in ancient days the lobster was unknown. Both of these creatures have claws and can travel in similar directions, forward, backward, or laterally. What's in a name then, since this disease would kill as quickly under any other name? The word cancer has come to be synonymous with death. To be afflicted is to die sooner or later, and with the knowledge that there is no help other than futile efforts, surgical in character, which tend only to postpone the death sentence but never permanently to cure the patient. If for no other reason than the awful fear and hopelessness with which the word cancer fills the sufferer this word cancer should become obsolete, and there are good reasons for discarding it. If the ancient physicians were ignorant about cancer and gave it this name there is no justification for our continuing to use it. Although we may have not learned much more than they already knew, which in particular was its certainty to cause death, we may in the light of modern psychology give it another name—a name which has some pathological significance. The writer suggests the term "malignant inflammation" because it is an inflammation of malignant type, and at no time from its inception to its complete cessation, through dissolution of the patient, does

it cease to be an inflammation. The pathology is clear and undisputed. No cancer was ever known to exist that did not have as its starting point some area of inflammation. No cancer ever passed from this stage without first going through the stage of a tumor, and the path of its progress is by four ways, namely, hyperemia, inflammation, tumor, and cancer, and it can be undeniably affirmed that there does not exist a cancer in which there does not also exist some degree of inflammation.

Because of the centuries that have passed by, leaving cancer incurable, the mind has come to look upon it as a real entity, as a thing with individual characteristics, and the histologists have helped to maintain this belief through their discoveries of the different types of cells in cancer. The thing itself cannot be isolated or separated from adjacent tissues, from the fact that no surgeon can tell where the line of demarcation exists between the cancerous tissue, the inflamed tissue, or the healthy tissue, and to make sure that all diseased tissues are removed a wide cut is the usual surgical method. Cancer is not a thing that can be enucleated as a pea from its pod or a cyst from its site. It is a condition, and is dependent entirely upon the factors which first incited the primary stage of inflammation.

Does it not seem from the foregoing that the proper treatment of cancer is by the channels best suited to subdue inflammation? Not with an effort to control the progress through local medication, but decidedly by means which will reduce the predisposing causes that bring about the original inflammation. If acidity is a factor or the actual factor, the things which cause this condition must first be removed. What better agent can there be in the human economy to produce acidity, or acidosis, than an excess of sodium chloride in the plasma and tissues of the body? The existence of hydrochloric acid in the gastric juice depends altogether upon the sodium chloride ingested with the food. An excess of this acid must be due to an excessive use of common table salt. What more suitable agent to incite inflammation in the cells than a plasma saturated with salt in which they are by nature obliged to live?

The splitting up of sodium chloride sets free the chlorine which engages in the formation of gastric juice, while the sodium, being a highly oxidizable substance, is soon consumed. There is, however, reason to assume that more sodium can be set free than the conditions present are capable of oxidizing if an excess of salt is used. Under such possibilities the cells soon become impregnated with sodium much to their detriment, since sodium is not the natural element of cell tissue, while potassium is. Furthermore, ingestion of the element sodium is augmented through the various salts of this substance which find their way in the preparation and preservation of perishable foods; for example, we find that not only sodium chloride is used to great excess but that soda in the form of the bicarbonate is commonly employed as a household remedy for acidity of the stomach. Along with this are other salts of soda as the benzoate, baborate, salicylate and baking powders containing soda, these serve as a fruitful source of supplying an excess of soda to the system, much-

beyond the capacity of the oxidizing and eliminating forces of the body to compensate.

Bock (1907), according to Cushny, injected an isotonic (1.1 per cent) solution of potassium salt intravenously in rabbits at a very slow rate, so that there was practically no hydremia, the solution being eliminated from the vessels as rapidly as it was injected. He also observed that "During the first diuresis the increase in sodium appears to be of the same nature as the increase of chloride when bromide is given, and the inference is that potassium displaces some of the sodium in the tissues and thus increases its concentration in the plasma and filtrate." The concentration of potassium in the plasma and filtrate was of course much lower than that of the sodium. His further experiments and the findings are of interest from the standpoint of the kidney, but have no special bearing here, however. Bock states that the "potassium salt is highly poisonous to the heart in anything over about 0.05 per cent."

The nitrates are not the only agents by which the chlorides may be displaced, for the sulphates equally enjoy this property. But in the treatment of cancer, allowing that the disease is caused by an excess of sodium chloride in the tissues, the main object is not only to displace the sodium and the chlorides, but while doing this to replace the potassium in the cell. The chlorides, nitrates, and sulphates are all diuretic, but "The unabsorbable sulphate always limits the reduction of the fluid below a certain level by offering osmotic resistance" (Cushny). Such an objection would not be present when the nitrates are administered; and because of their solubility they are to be preferred, and in the form of salt such as potassium nitrate.

According to the principle of maximum work in thermochemistry, which was demonstrated years ago, whenever several chemical reactions are possible, as the result of the admixture of various chemical reagents, the reaction which takes precedence over all the others is that which leads to the greatest development of heat; or in other words, the particular chemical compound will be formed first whose so-called "heat of chemical formation" is highest; and that compound will also be the most stable, or the most difficult to decompose or displace. When nitrate of potassium, composed of potash and nitric acid ions, enters the plasma of the blood, which always contains chloride of sodium, it is possible for a double decomposition to take place, by which potassium chloride and sodium nitrate are formed. Now, it so happens that the heat of formation of potassium chloride is higher than that of sodium chloride, except chloride of lithium (which is only about 1 per cent. higher, and is of no special interest in the present connection because it is not a natural constituent of blood or tissue), consequently, according to the established recognized principles of thermochemistry, not only will there be a tendency to the formation of chloride of potassium (by virtue of the principle of the tendency to maximum heat development just mentioned) but this salt will be a more *stable* constituent of the blood or of any of the fluids or tissues of the body than chloride of sodium.

At the same time that chloride of potassium is formed by the union of the potassium ions with the

chlorine ions of the chloride of sodium present in the fluids of the body, the nitric acid ions, let loose or released from the potassium nitrate, will combine with the sodium ions of the chloride of sodium, forming nitrate of sodium. This substance can pass out of the cell tissue into the blood and take part in other chemical reactions in which nitrogen plays an essential rôle.

An interesting circumstance in connection with the exchange of ions taking place between chloride of sodium and nitrate of potassium, is that the sum of the heats of formation of the two end products remains substantially the same as the sum of the heats of formation of the two initial products. This means that very little energy needs to be supplied from the blood, or from other sources of physical or chemical energies of the body, in order to effect the double reaction just mentioned.

According to White's *Materia Medica*, potassium nitrate, owing to its high diffusive power, quickly passes into the blood unchanged. It is classed as a powerful cardiac depressant, causing the beats to become feeble and fewer. Large doses lead to great weakness, fainting, and death. Small doses are diuretic from their direct action on the renal cells. The dose is given as five to twenty grains. The drug is excreted unchanged in the urine.

Loewi (1902) quoting from the *Secretion of Urine* by A. R. Cushny, states that the intravenous injection of nitrate caused an increase of the chloride excretion. This fact might give rise to the question as to whether it might not be possible to remove too much salt from the body below the physiological amount required to maintain health, but this seems improbable as Cushny remarks, "That some constituents of the plasma are only excreted in so far as they exceed a certain threshold value," and in another passage he says, "The elimination of one constituent of the plasma which is present in excess does not necessarily involve changes in the others." For example, he continues, salt added to the food is excreted in the urine and the total chlorides increase, but the amount of urine and of the other constituents may remain unchanged; the percentage of chloride of course increases. But it not infrequently happens that excess of salt in the food leads to an increase in the water of the urine, and the percentage of salt in it remains unchanged while the total salt rises; the other constituents remain with little change in absolute amount, but the percentage falls from the increase in the water. This variation in the behavior in the kidney as to salt is probably more apparent than real. For the salt is presented to the kidney not as it was ingested but as it occurs in the plasma; if the salt has passed into the blood without much disturbance of the circulation of the blood and lymph, it comes to the kidney in the form of a slight excess of chloride in the plasma. But if exchange currents have been set up between the tissues and the blood, the plasma reaching the kidney may have excess of both water and salt, and both are eliminated together. The difference in the reaction arises from the varied activity in the tissues in general and not from incontinence of the kidney.

It follows then that removal of the excess of the chlorides should be accomplished with safety. It is

probable that, after the administration of potassium nitrate the excretion of this salt in the urine would be less than the amount ingested, and this could be accounted for by assuming that the potassium had taken the place of the sodium in the tissues. It would seem reasonable not to expect any of this salt to appear in the urine as an excess until its threshold value had been determined by the cells. It should be borne in mind that at no time will the cell part with any of its constituents until the amount exceeds its threshold, and that the cell may exist this is self-evident, for were it to part with any one ingredient, or portions of all, it would have no stability as an existing thing and so cease to be; in other words, it would evaporate.

The most ideal manner to administer potassium nitrate for the treatment of cancer would be by hypodermic injection, and the dose should be proportioned according to a limit of safety, bearing in mind that a solution over about 0.05, according to Bock, is poisonous to the heart. However, there is no record of this drug having been given hypodermically, so that the dose would have to be adjusted to suit the individual condition of the patient, and this must depend entirely upon the judgment of the physician.

White, in his *Materia Medica*, states that, "External to the body, nitrates prevent coagulation of the blood, or dissolve the clot if it be already formed; but it is not known that they have any effect on the blood in the body."

These cautions regarding the use of potassium nitrate are merely mentioned from the standpoint of information, and are not set forth with the idea of fostering fear in the mind of the physician who might give a hypodermic injection of the drug, and thus create in his mind a bugbear of the possibilities of an embolus.

The writer in the past seventeen years has administered hypodermic injections of various substances, other than potassium nitrate, in nearly every accessible part of the body, including such unusual regions as the scalp, cheeks, throat, and neck, and going very close to some of the large blood vessels lying there, but he has yet to observe the first symptom indicating the occurrence of embolism. A similar experience can be cited in the practice of a veterinary surgeon who stated that he had repeatedly tried to create emboli artificially in the veins of dogs, by injecting air, but had never succeeded in doing so, and remarked that he did not think emboli could be artificially created. This, however, might not be the general belief or experience of physicians, and the suggestions given here may be accepted for what they are worth. Nevertheless, hypodermic injections, as a rule, are considered free from danger.

There are many important reasons why nitrate of potassium should be administered in minute doses and highly diluted in water. On the one hand, the introduction of salts of potassium into the blood at too great a rate is objectionable because of the toxic action on the heart; this action becomes more marked when the quantity of potassium salt contained in the blood exceeds about 1/20th of one per cent. The moment the quantity of potassium salt present in the blood exceeds the proper physiological limit, the excess is worked off through the

kidneys by increased secretion of urine containing a higher percentage of potassium than normal. On the other hand, dilution of the solution containing potassium nitrate accomplishes several important objects. First, the process of osmosis by which alone this salt can pass through the walls of the intestine into the blood is greatly facilitated. A strong solution of the salt would indeed pass through only quite slowly if at all, and the more it is diluted the more readily it will pass. As a matter of fact, the more nearly the solution approaches the specific gravity of pure water the more readily it will pass. What is true of the osmotic action by which passage is effected into the blood from the intestines, is even more true in the case of the osmosis by which substances are transferred from the blood into cell tissues through the walls of the capillaries. It is quite conceivable that although the blood may contain a given salt in considerable amount, very little, if any of it, may pass into the tissues. Indeed, paradoxical as it may seem, in certain circumstances the greater the quantity present in the blood, the slower the rate of its transfer, and therefore the smaller the amount transferred in a given time. This underlying principle of physical chemistry is perfectly well established and should be employed more generally when administering substances whose medicinal effects are dependent upon the property of osmosis.

Second, the chemical reactions on which the therapeutic actions depend are also much facilitated by dilution. The effect of dilution, it is well known, is to produce a state of partial "dissociation" or "ionization" in the elements of a salt held in solution in water, so that some of the atoms are less tightly linked, or less intimately bonded together, in other words, they are partially freed from each other, and exist as "ions," and when in that ionized state they are more susceptible to the action of all reagents and reactions, whether chemical or physiological, which tend to cause chemical changes in them. It is well known that dissociation and ionization render possible many chemical changes and reactions that cannot be produced otherwise.

The foregoing considerations are logical and scientific, applicable not only in this case, but almost in every case where therapeutic agents are to be administered in liquid form. They point to the desirability, in the general case, of not letting the remedial agent cause congestion and crowding, either at the entrance-gate through which they pass into the blood, or at the outlet-gate through which they pass out of the blood into the tissues or into the secretory or excretory organs. A cardinal principle that should be borne in mind is that it is not the amount administered, but the quantity which can be *effectively* utilized that counts. Whatever portion has no chance of being effective had better not be administered, but the dual reason that not only is it in the way and prevents the action of the rest, but the task of eliminating the excessive and useless portion may impose more or less serious, and at best always objectionable, work on the heart and the other organs of the body.

Since the object sought is to replace sodium chloride in the tissues by potassium chloride, and since the end-reaction obtained, when potassium nitrate is administered, is the formation of potassium

chloride, the idea will suggest itself quite naturally of giving potassium chloride directly instead of potassium nitrate. But if this is done the potassium chloride would remain in the blood almost entirely, or, if it passed into the tissues, it would not replace or displace the sodium chloride other than in a mechanical way, whereas the potassium nitrate acts chemically by causing actual removal of the sodium elements of the sodium chloride already in the tissues, and their replacement by the potassium elements of the potassium nitrate, at the same time that the displaced sodium elements are removed by combination with the nitric acid elements of the potassium nitrate to form sodium nitrate. The effect of this double reaction is to introduce the potassium in the tissues in the most stable form, namely, potassium chloride.

There appears to be no other salt which can serve the same purposes as the nitrate. If one should be found later it would probably have thermochemical properties very near those of the nitrate, and the acid radical would probably have as good solvent power for sodium as nitric acid has. There are potassium salts which approach the nitrate in one or the other of these two important respects, but the researches made by the writer have thus far failed to bring to light any other salt that fills the requirements as fully and as satisfactorily as the nitrate.

The weakness of carbonic acid and of acetic acid, as compared with nitric acid, explains at once the unsuitability of the carbonate and the acetate salts of potassium as substitutes for the nitrate. The same criteria would apply in determining the relative suitability of other potassium salts. Take, for example, potassium carbonate. Owing to the fact that its heat of combination is lower than that of potassium nitrate (92.4 calories as against 96.1), it would be expected that it would react more promptly with sodium chloride to produce potassium chloride (100.8 calories) because the heat set free is greater when starting from 92.4 than from 96.1 calories. It is known, as a matter of actual test, that the reaction is much more prompt. Unfortunately, however, the end products are not suitable. The carbonic acid of the potassium carbonate and the sodium of the sodium chloride are set free independently instead of uniting and forming a new compound, sodium carbonate. The result is that the blood, or the cell tissue in which the reaction takes place will contain free carbonic acid and sodium hydrate, both of which, it is needless to add, are highly objectionable and must be eliminated, the first through the lungs and the second by the kidneys. This illustration of the importance between the action of the nitrate and other salts of potassium emphasizes the great importance of understanding and bearing constantly in mind the possibility of deleterious effects due to primary or secondary chemical reactions which may take place between the remedial agents administered and the blood or the tissues.

Now, from what has been stated, the most logical deduction to be made is that if potassium nitrate is administered the sodium chloride will be displaced, and the cells relieved from the irritant action of the sodium chloride, would lose their malignancy and continue toward physiological

repair, and recovery would be the inverse of the manner in which the disease developed. That is to say, starting with a hyperemia, followed by inflammation, which progresses into tumor formation, and then into cell degeneration recognized as cancer, the first improvement would be noticed as a sloughing away of the malignant or dead cells, the repair or waiting cells being at the point of mitosis would become constructive and as soon as the lesion had healed all inflammation would disappear. The cancer lesion would take on the characteristics of a traumatic wound in the process of healing. Local treatment such as the application of the Dakin solution followed by appropriate surgical dressing would complete the cure of the case. The Dakin solution hastens healing by dissolving the dead and poisonous tissue and matter while not injuring the living tissues.

Regarding potassium nitrate from the viewpoint of a therapeutic agent in the treatment of cancer, the writer feels that enough has been offered here to show reasons why this drug should be given a trial. In the past, the internal treatment of cancer, decidedly meager and undoubtedly empirical, has not been productive of any remedial advantages from which a system of treatment might be formulated, and if perchance there were evidences of improvement or of cure in any given instance no logical reasons for such phenomena were forthcoming.

But in this instance we start with the hypothesis that sodium chloride is the cause of cancer, and we learn that potassium nitrate is effective in displacing this substance in the manner already described, namely, that the nitrates displace the chlorides, and the potassium salt displaces the sodium salt, and at the same time takes the place of the sodium salt in the cell, of which it is a natural component. The generally accepted view then, that all medicine is more or less empirical, may in this instance lose weight from the fact that the cause of the disease is known and the reason for the action of the remedy for its cure is also a matter of knowledge, and this in spite of the fact that no less an authority than Osler himself has said that "We medical men know little or nothing of the real action of drugs, and we put them into bodies of the action of which we know less." Be this as it may. When it is realized that the death rate of cancer has almost reached the appalling number of one hundred thousand lives yearly, and that in New York City alone the weekly average of deaths from cancer and malignant tumors is in the neighborhood of ninety, it would seem that any drug which offered the slightest hope in ameliorating this awful scourge is deserving of trial, and potassium nitrate seems to the writer the most logical one to try.

452 FIFTH AVENUE.

Influenza Meningitis.—According to Lorey but few cases of this affection are upon record and these purulent and in children only. He describes a case which illustrates quite a different type. A woman aged 49, in the midst of health, was stricken with meningitis which ended after six weeks in recovery. The lumbar punctates were all clear, but in the sediment influenza bacilli were found and readily cultivated.—*Correspondenz-Blatt für Schweizer Aerzte.*

SOME OF RABELAIS' IDEAS OF THE STOMACH.

By DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO.

RABELAIS' ideas of the stomach were necessarily very crude; he knew of the existence of the organ, and that it was a bag for the reception of food. The knowledge of those who had preceded him seems, however, to have been cruder than his. For example, he draws attention to the fact that drink flows over the tongue and down the esophagus into the stomach, and not down into the lungs by way of the rough artery (the trachea), as was the opinion of Plato, Plutarch, Macrobius, and others.¹ The drink, le boire, referred to was water, but a peculiar kind of water, that resembled wine of any kind which the man drinking it might desire. It therefore had the attributes of wine.

Wine (alcohol) was not then regarded as it is to-day, as a poison generated by the action of micro-organisms on sugar, but as a spiritual essence easily transubstantiated into an infinitely more highly spiritualized fluid, the blood of Christ. It would be perfectly logical, therefore, for a mystic to believe that the highly spiritualized fluid, wine, might take the same route into the body as the spirit, air, the Breath of Life. Rabelais' correction of this view, therefore, was probably not an idle remark. This applies to many a remark by Rabelais, in appearance most idle, in substance most grave.

The Idea of Hunger as Referred to the Stomach.—Hunger is a most interesting phenomenon, both politically and personally. The earth has been called the hungry planet.

Actuated by the electromagnetic energy of light, everything seems to be anxious to combine or to dissolve combination with its neighbors, and in the processes in the corporeal workings of the more highly organized animals the sensations of hunger are developed. In starvation, every cell in our body calls for food, but the principal sensations refer to the stomach. As each organ, however, when irritable or irritated gives rise to the sensations peculiar to it, as, for instance, the sensation of itchiness in an irritable skin, so an irritable stomach, as in gastritis, may feel hungry even when the individual is not in need of food.

Ingenious experiments have shown that the pangs of hunger are associated with strong contractions of the stomach, and sympathetic ones in the bowels, causing rumblings due to shifting gas. Long previous to the demonstrations of the hunger contractions by the x-ray, literary men, as not being totally unacquainted with the sensations of hunger in their own persons, have poignantly described these pangs and rumblings. The phrase, "The clamors of the stomach," is a frequent mode of expressing intense desire to eat, and Merlin Coccaie, in his "Histoires Macaroniques," says that "Falcquet felt in his belly that his entrails were empty; his stomach cried out." And in another situation he says, "My belly growls with hunger." Rabelais repeatedly mentions the braying, bawling, and barking of the stomach because of hunger.²

A very interesting circumstance in regard to the sensation of hunger is that absolute fasting is said

by those who have suffered it to be not distressing, while insufficient feeding is productive of real suffering. The most harrowing stories of misery endured by Arctic explorers, for example, refer rather to short rations than to downright starvation.⁴

The desperation to which hunger leads impressed Rabelais profoundly, and he has written an eloquent chapter on the absolute dominance of Messer Gaster, the stomach king, who has no ears, and hears nothing whatever, and before whom, although he speaks only by signs, all other lords, kings, and governors bow in obedience.⁵

Rabelais quotes Hippocrates as saying that youth is impatient of hunger, chiefly if it be vigorous, lively, brisk, stirring, and bouncing.⁶ The aphorism alluded to reads: "The elderly are the most patient of abstinence; after them come those in full adult life; the adolescents are highly impatient, and infants have no patience at all, especially those who are the most vivacious." Hippocrates evidently had heard the strident cry of the hungry baby.

The Delights of the Stomach.—The miseries caused by hunger are great, but an appreciation of delights attendant on the satisfaction of the appetite are of more importance to the physician. It enters into his daily work to satisfy this desire, and at the same time to secure the observance of temperance along the lines he wishes, in order to bring the patient back to health.

Appetite is different from hunger, and may be described as a pleasurable normal desire for food, while hunger is a painful craving. Rabelais, in his description of the physiology of digestion, says that appetite is caused by a little sharp black bile transmitted from the spleen. It acts on the orifice of the stomach, admonishing it to lay in victuals.⁷

This black bile, which was so very important in the conception of the bodily functions in the old physiology, was never demonstrated. Two centuries later, when the Galenical system was breaking down, and when ardent Galenists were forced to admit they had never seen the black bile, they evaded the question by saying that possibly nobody had seen it but Galen, and that if he had not seen it he should have done so, and there was an end to the matter.

On an island, Pantagruel encountered a race of men who worshipped the aforementioned omnipotent sovereign, Messer Gaster. They were a strange generation, some merry, dainty, soft as down, others sour, grave, severe, and glum. They were alike in working not at all, and in being a weight and useless burden upon the earth. They were called gastrolaters, or belly worshipers.⁸

Friar Jean cannot be included among these belly worshipers, although he was a generous feeder and a famous drinker. At a feast given him by Gargantua he acknowledged that so far as liquor was concerned he had a paved stomach, as hollow as the bottle of St. Benedict, and always open like a lawyer's pouch. A lawyer's pouch is called *la gebecière d'un avocat*, the game bag of a lawyer, an excellent and appropriate designation.⁹

Pastimes During a Calm at Sea.—In a dead calm at sea, Pantagruel and his companions encountered difficulties in passing their time. They fell to asking how certain things might be done. For instance, Xenomanes, who seems to have been rather stout,

inquired how the stomach might be so balanced as not to tip more to one side than to the other.¹⁰ This idea may have come to Xenomanes from the rocking of the ship. Furthermore, it is a real physician's problem, repeatedly presented to every one of us, either on the operating or on the examination table, and is only one of many indications showing that Rabelais was undoubtedly a practising physician. This is an instance where the word "stomach" is made to include the whole abdomen, a frequent use of the word even at the present time.

Prostatic Abscess.—The subject for general discussion at the IV. Congress of the Spanish Urological Association, held at Madrid, Oct. 24-28, was prostatic infection (exclusive of gonorrhea). It was subdivided into acute and chronic infections and tuberculosis. The paper was read by Dr. Baragán of Madrid who reached the following conclusions: All of the diseases of the prostate predispose to secondary infection. In 80 per cent. of cases prostatitis is secondary to posterior arthritis and 80 per cent. of the latter affection is curable by medical treatment. In abscess formation the condition is severe and demands early operative relief and the higher the seat of the pus the more grave is the condition. The perineal route is the choice for intervention. In spontaneous rupture into the urethra the condition is more benign than when rupture occurs into the rectum. If the rupture occurs above, the outlook is much more serious. The author reports 55 cases of prostatic infection, exclusive of gonorrheal and tuberculous material. Of this number 36 were due to the use of infected catheters and to false passages, 4 were secondary to rectal processes, 4 to foreign bodies in the urethra, 8 to renal and vesical affections and 3 followed perineal section.

In discussion Esquivel reported a case of prostatic abscess complicating typhoid fever. Pus in large amount escaped from the urethra. The condition healed under urethral and rectal irrigation. Miravel reported a case of prostatic abscess in an old subject due to the presence of an intraprostatic calculus and a second case in a typhoid fever subject with Eberth's bacillus in the pus. Cifuentes reported cases of abscess which followed nephrolithotomy and perineal section respectively. Negrete reported cases of abscess due to *B. coli*, and Sánchez de Val a case in which operation on a periprostatic abscess failed to relieve symptoms of general sepsis. A second operation revealed a focus of pus within the prostate. Alcina mentioned a case in which massage of a prostate caused escape of pus into the urethra; also a case of abscess following a fall on the perineum. Pérez del Terro narrated cases of abscess secondary to rectal lesions (piles, fistula).

Military Medicine.

Accidents from Inhalation of German Gas.—Cheyrou (*Journal de médecine et de chirurgie pratiques*, February 25), states that after a bombardment with gas shells, one may see mild cases of gassing change suddenly for the worse. He wishes to study especially this type of case by itself. It is not a question of the typical results of gassing or the new forms of gas, but of certain recent effects of bombardments in Argonne. The gas shells were composed of palite and the agent which caused the symptoms was the chloroformate of monochlorated methyl. In some subjects after gassing the predominant disturbances were digestive, in others respiratory. In some subjects the degree of intoxication may be estimated by cardiac symptoms and in others by depression and general fatigue. The main feature is that whatever the symptoms they may be so mild as to seem insignificant. The sequelæ comprise cardiovascular phenomena, cardiac fatigue, and pulmonary tuberculosis. Hence even those with minimal symptoms should be evacuated to the rear with the aim of forestalling or minimizing these sequelæ. Of two bombardments in succession suffered by a certain battalion, the first caused plenty of initial troubles, but no sequelæ. It was necessary to evacuate a number of troops because they were temporarily unfitted for duty and as soon as they had recovered they returned to the front. Many were treated without evacuation. The next bombardment followed at night with a mixture of explosives and gas shells. The troops complained of their eyes, respiratory passages, and digestive tract. No burns were visible. The predominance of intestinal over respiratory symptoms in some cases was due evidently to swallowing of the gas. The symptoms passed off slowly and everything went ahead as if nothing had happened. As the ground and air are infected with gas to some extent the areas of explosion were disinfected with dry chloride of lime. During the next few days the symptoms which persisted in a number of the men were very slight and required only the simplest remedies as bicarbonate of soda for the stomach, mentholated vaseline for the nostrils, etc. About nine days after the gassing the bicycle messenger who had given the alarm of the impending bombardment was seized suddenly with dyspnea and was found to have a stitch in the left side and dullness of the left base. He was at once evacuated and became steadily worse. He had fever, tachycardia, sputa of apricot color, progressive increase of dyspnea, delirium, ending in death in asphyxia. The usual remedies gave no relief. The lesions were those of simple total congestion of both lungs and of all the viscera. Death was pronounced due to palite. Two men exposed with him got off with bronchitis—one had an attack of pulmonary edema—and were soon back in the ranks. These palite shells explode feebly after a long hissing sound and the vapor does not appear to penetrate the soil. The odor suggests perfume of sweet almonds. The substance appears to linger in the neighborhood, disappearing but again returning if the air becomes humid. It resists the action of disinfect-

tants and the earth when examined shows no trace. The tactics of the Germans seem to be to mix gas shells in variety, each having different properties. The apparently inoffensive gas with mild explosive force, odor, and initial symptoms may readily go unrecognized. The bicyclist was nearly 40 years old and his age may explain his greater vulnerability, for the younger the man the more resistance is offered by his heart. The extensive congestion of the lungs throws a great strain on the latter. Ordinarily venesection, camphor, and perhaps sparteine would have disembarassed the heart.

Meteorism in Italian Soldiers.—Cecconi, in *La Riforma Medica* for February 23, finds that the military "big belly" which has attracted more or less attention, possesses a medicolegal significance. Pisani, a student of the subject, ascribes the condition to spasm of the diaphragm. But there are no pulmonary symptoms to suggest respiratory insufficiency on the one hand, and abdominal breathing is seen to go on. The picture in no way corresponds to what we know of diaphragmatic spasm, which, moreover, is extremely rare and probably psychogenic meteorism from whatever mechanism is common in hysteria and the diaphragmatic theory has been invoked in this connection.

The author, who has been studying this condition for thirty months, cannot rid himself of the belief that this meteorism is largely artificial and simulated. In one group of cases the subjects are sound and well nourished and aside from the meteorism have no complaints. Placed in dorsal decubitus the meteorism which before seemed more pronounced in the upper abdomen, is seen to be somewhat lower placed and less marked when the patient stands the condition is augmented. Palpation of the lower abdomen reveals a strongly arched lumbar spine. Respiration seems superficial with occasional deeper breath and chiefly thoracic. In the deep inspirations the diaphragm contracts. Under persistent palpation abdominal resistance diminishes, its volume becomes less, while the lumbar prominence seems flattened. The mental status recalls that of the simulator. The control of the flexibility of the spine which almost equals that of the contortionment, together with the possibility of control over the diaphragm, oblique and transverse muscles suggest unusual voluntary, perhaps unconscious manifestations.

The soldier's big belly has been studied in the French army and attributed to a simple voluntary contraction of the diaphragm. Voluntary or natural obstipation and air-swallowing may, of course, lead to meteorism. In no x-ray case of the authors was there any evidence of tonic spasm of the diaphragm, although he has seen it in subjects who had no meteorism.

In a second, less numerous class of big bellies the abdomen is uniformly distended and highly resistant to palpation. The percussion note frankly tympanitic and from time to time there are eructations. The diaphragm is compressed and the functions of the entrathoracic organs prejudiced. The x-ray shows a high position of the diaphragm. This class of patients seem to be air-

swallowers pure and simple, and probably simulators in part. There is a third class which as yet has not been much studied. The meteorism is perhaps limited to the colon so that the flanks are principally involved. These cases are residual and only a few were studied, so that their status is obscure. They may be vagotonic subjects and a vagotonic component may be present in all of these cases. The author does not write of any patients charged with simulation, and it seems that thus far he has not "got the goods" on them.

Bone Grafting for Closing Openings Following Gunshot Wounds in the Skull.—Lieut.-Col. C. G. Morice, N. Z. M. C., writing in the *New Zealand Medical Journal* for December, 1917, says that since the adoption of the metal helmet for soldiers the number of the non-fatal head cases has greatly increased and the need for late operation has been correspondingly more marked. During the six months previous to the writing of the paper nine cases presented themselves at the Victoria Military Hospital with various nerve symptoms, following upon wounds resulting in the loss of portion of the cranial bones. Three of these were advised not to have operation, as their injuries were recent and their symptoms mild. The other six were so seriously handicapped as the result of their injuries, and drugs having completely failed, that it was necessary to take radical measures to improve them. The symptoms vary considerably, according to the position of the injury, etc., but the following list includes all that have been complained of: (1) A feeling of insecurity and nervousness and especially dread of a blow on the head; (2) fear in crossing a street or when left alone; (3) giddiness on stooping or turning round; (4) loss of consciousness with more or less epileptic symptoms; (5) general malaise, loss of memory. One patient had uncontrollable fits of temper, the possible results of which frightened himself as well as his relatives. Various substances have been suggested at different times for filling up gaps in the skull, but up to the present time pieces of periosteum-covered bone are most in favor. Thus in 1915 Murphy used flaps of fascia and fat taken from the thigh, but admitted that he got improvement in only about 5 per cent. of the cases. Portions of the scapula with periosteum on both sides have been used, also pieces of rib, which certainly have a useful curve; and just recently rib cartilage has been recommended in the *British Journal of Surgery*. The outer table of the skull alongside the aperture has been separated from the inner and swung over to cover the opening; plates of silver, perforated celluloid, and other material have been well spoken of, but Morice has been quite satisfied with pieces of periosteum-covered tibia, especially since using the electrically driven saw recently introduced into the Wellington Hospital.

The scalp, after being shaved twice at four or five days' interval, is thoroughly cleaned by the spirit and iodine method. The head is then covered with a sterile cloth, a tourniquet applied, and a curved incision made through cloth and scalp down to the pericranium. The flap is turned back and the pericranium incised one-eighth of an inch outside the margin of the defect. The

membrane is then reflected inward and outward for about half an inch. The outer table of the skull is removed all round the aperture by means of gouge and mallet for about the same distance. The size of the prepared area is carefully taken, hot swabs are applied and the flap of scalp turned back into position while the graft is being prepared from the leg. The subcutaneous surface of the tibia is exposed by a slightly curved incision convex backward. The periosteum is incised round an area one-quarter of an inch larger than the dimensions taken of the cranial defect and reflected inward to the same extent. With a circular saw a graft is cut with very beveled edges and detached by means of a broad chisel. If necessary to obtain a considerable curve corresponding to that of the skull, cross cuts are made with the saw and the piece of bone, bent or even cracked across. The periosteum of the graft is sutured to the pericranium all round and the flap of scalp replaced in position. A large sterile dressing applied with moderate pressure is used and need not be changed for ten days. At the first dressing some effusion may be found under the flap, but is easily let out, and there should be no further trouble. The leg wound is generally complained of as being much more painful than the scalp and may require hot fomentations and considerable elevation for a few days. As soon as the patient is able to let the leg hang down he is allowed out of bed and this is generally about the end of the second week.

Testing the Heart for Military Service by Sprint Racing.—Karcher writes of the Swiss military service in the *Correspondenz-Blatt für Schweizer Aerzte* for March 16. Many tests for cardiac sufficiency have been tried out since the war, but evidently the subject is far from complete. Recently experiments have been made for all ages of troops, which were at first practiced only in new recruits. They consisted of 100 meter running competitions. In certain cases light work preceded the sprints, consisting of the twenty genuflexions, etc. Four classes of men were isolated after the tests, as follows: 1. Those unable to finish the distance; 2. those who finished with marked dyspnea; 3, those who looked bad as a result of the effort, and 4. those whose pulse and respiration had not become normal after two or three minutes. These classes were then minutely examined for possible nasal affections, goitre, cardiac and pulmonary lesions, renal affections, and bad feet. The original tests on 100 recruits, who represented much variation as to occupation natural vigor, etc., gave mostly good results. Exceptions were due to weak feet, varicose veins, goitre, and isolated cases of organic heart disease and probable tuberculosis. The average pulse rate after the race was 138 variations, being from 100 to 162. Rapid recuperation was seen in a third of the men and one man in eight had not recovered pulse equilibrium after five minutes. The general impression is that there is no such thing as a standardized recruit, personal equation playing havoc with records.

In regard to the troops proper no distinction was made between the regular mobilized army and the landwehr. The men tested were all moun-

tain troops, from whose ranks the unfit had been largely eliminated. After application of the test four classes were isolated, to wit: true cardiacs, subjects with extracardiac circulatory disturbances, tall, weakly, prematurely exhausted marching troops, and prematurely aged men long in the landwehr. Among the cardiacs the tests were made despite the fact that the men were already known to have effort dyspnea, etc. Such individuals, however, may stand the race fairly well. In a soldier in his forties the pulse was 164 after the effort, but two minutes later had dropped to 78. As sometimes happens, however, the pulse shot up again after 5 minutes and dropped more slowly than before. A single test two minutes after a race may therefore be fallacious. Not only must it be repeated, but other factors may outweigh negative finds. The tall, slender young marching troops who tire readily and react badly after the running tests were found to give a positive reaction. The prematurely old landwehr contrasted strongly with some of their fellows of the same age, a fact attributable to poor hygienic and economic conditions and perhaps abuse of alcohol. Reaction after the race was variable. In the majority the blood pressure was low for the age (the normal average for the landwehr is about 125 mm.). In the extracardiac type of circulatory disturbance the presence of goitre plays a rôle, that disease being endemic for the locality. Evidently the sprint race has not been tested sufficiently to reach general conclusions. It is not dependable as a sole test and its value seems to lie in the direction of a good emergency test for weeding out doubtful cases.

Pediculosis and the War.—Dr. H. H. Hazen, writing in *Medicine and Surgery* for February, 1918, referring to pediculosis, says that it is an almost universal affection of the men in the trenches. Not only may the pediculi carry the germs of typhus, but they also carry ordinary pyogenic organisms and secondary skin infections are frequent. In the old days we were led to believe that if a person wore some roll sulphur beneath his clothes the chances were that he would not be troubled by lice, but this beautiful theory has been absolutely destroyed. One important new discovery is that of Semon and Barber (*British Journal of Dermatology*, 1917), namely, that the body lice frequently deposit their nits in the pubic hairs, and that these must be destroyed in order to rid the person of his infection. Gasoline is excellent for this purpose or a carbolic acid lotion will do almost as well. Many insecticides have been suggested. Castellani and Jackson (*Jour. Trop. Med. and Hyg.*, 1915) state that for use on a large scale the best powder is naphthalene, but that for a better class of patients menthol is preferable. Other substances possessing merit are kerosene oil, lysol, camphor, oil of turpentine, anise oil, powdered pepper, and oil of cloves.

Casualties in the American Army in France.—The casualty list given out in Washington shows that from the time of the engagement of the American Army in actual warfare in the French front until April 26, 552 men have been killed in action and 128 have died of wounds. During

this same period 945 have died of disease, 198 of accident, and 94 from other causes. There have been 467 severely wounded, 1,654 slightly wounded, and 86 are reported as missing.

College for War Hospital.—Richmond College, at West Hampton, Va., has been turned over to the Government for use as a military hospital. The college will occupy buildings in Richmond.

Lectures for War Department Employees.—Surgeon General Gorgas has arranged for a series of "Half Hour Health Talks" for the civilian employees of the War Department. These lectures are to be held Tuesday and Thursday afternoons at 4.45 o'clock, in the auditorium of the Department of the Interior. The lectures will be illustrated and will be given by officers of the Medical Reserve Corps of the Army.

War Nurses Plead for Military Rank.—A large delegation of women and Army Medical Officers appeared before the House Military Committee on April 16, for the purpose of advocating the proposed legislation which would confer military rank on war nurses. The following ranking has been proposed: Superintendent of Nurses, Major; Assistant Superintendents, Directors, and Assistant Directors, Captain; chief nurse, First Lieutenant, and head nurses and nurses generally, Second Lieutenants.

Lieutenant John S. Abbott, a St. Paul physician and instructor in the University of Minnesota, is reported as missing after the engagement of March 24 in France. Dr. Abbott enlisted in the British Medical Corps before the United States entered the war and has been in service in France for several months.

Summer Hospital Course.—Teachers' College, Columbia University, announces summer courses under the auspices of the Government for the training of reconstruction aids for the military hospitals. The course will begin on July 1 and will last six weeks. It will offer the opportunity for specializing in occupational and physical therapy.

Ophthalmic Hospital Makes War Plans.—The Directors of the New York Ophthalmic Hospital announce that plans have been made for specialization in the treatment of eye, ear, nose, and throat conditions in soldiers and the dependents of soldiers.

Lieutenant George Francis Patton, M. R. C., U. S. A., attached to the 165th Regiment, the old 69th, has been decorated with the Croix de Guerre for bravery. During a heavy bombardment from the German batteries, in which gas shells were being used liberally, Lieut. Patton found that his gas mask hampered him in the dressing of wounds, so he removed the mask and went on working over the wounded until he was overcome. Dr. Patton was a graduate of the Baltimore Medical College in 1910, and at the time of entering the Reserve Corps was assistant attending surgeon to the Bronx Eye and Ear Infirmary.

Health of the United States Army.—In an address delivered recently in Chicago, Surgeon General Gorgas is quoted as saying that the United States Army has surpassed the record of the Japanese Army, heretofore considered the model of the world, in holding down the percentage of disease among its forces.

DEVELOPMENTS IN INDUSTRIAL PHYSIOLOGY.

NONE of the remarkable scientific developments of the modern age can receive just recognition without a clear understanding that neither new discoveries nor development of present achievements can long go on without the intervention of better and stronger human beings—unless greater attention is paid to the physical needs, physiological and psychological requirements of the individual. Otherwise achievements are retrogressions rather than progress. All human effort is really purposed for the improvement of the human being and the making of this world a better place for him to live in. There is none that is nearly so intricate as the human machinery, and if modern developments in science are anything they are the means of bringing this intricate human machinery to the fore and harnessing it to the requirements of industry, the needs of the battlefield, or the needs of the home. But while the human machinery can be worked at various speeds and accommodated to various vocational needs its usefulness is closely limited by its liability to fatigue. And any efficiency development that has in mind only quantity and quality of material production or machine efficiency, and ignores the human element which necessarily controls, becomes the height of inefficiency. Large industrial organizations are beginning to understand this and much of their newer progress in organization and operation is planned with this in view. But this understanding must take place everywhere, in all industries particularly, before the maximum good will come of it. Progress in the development of human efficiency must be commensurate with the progress in industrial or mechanical development.

Inquiry into the human capabilities for work is intended to determine with what tools he can best work, during what hours he works best, when most fatigue is likely to occur, under what conditions he works best, etc. The Committee on Industrial Fatigue is now carrying on investigations in conjunction with the Public Health Service. In estimating fatigue of workers results are apt to be confused by the fact that voluntary effort may for a time increase the output beyond the real capacity,

while voluntary effort may reduce it below the normal capacity. In an ordinary muscle under stimulation there is a gradual rise in lifting power to a maximum and then a gradual fall. In the human organism as a whole, however, many conditions affect this curve to make it more intricate. Yet the more intricate a work and the more it requires coordination, the nearer this curve will be to that in the single muscle. After rest and food the curve of work is likely to reach a higher maximum than before it, both because of this fact and because of the practice, but the fatigue drop at the end of the day is usually much lower than that at the end of the half day because of the cumulative effect of the fatigue products. It would appear that the first effect of these findings would be to accommodate the most intricate and trying work to the period of maximum capacity and the less important work to the fatigue stages. However, nearly every occupation is defined by its own characteristic curve. The allotment of work must, therefore, be made accordingly. Yet no two days can show the same curve of work. When the daily curves are found to be uniform there must be a strong suspicion that the workers have voluntarily limited their speed and the amount of production. The curve of work would then not be a natural one but a voluntary one, and unless recognized as such would be confusing. Wherever a pronounced spurt is possible at one time, it shows that heretofore the maximum of natural capacity had never been reached.

It is the aim of investigators to determine what the limit of capacity is in certain occupations and under certain conditions, so that there will be neither an overtaxing nor an undertaxing of the human capacity. Unless the maximum capacity is determined there must be waste of time and energy, or destruction of vitality, as the case may be. It was found in Great Britain that the attempt to increase output by increasing the hours of labor and by overspeeding did not in fact result in an increase. In a great many instances the total output was less. Within limits it is difficult to determine the allowable number of working hours. But excessive working hours can always be counted upon to produce greater fatigue with ultimate loss in efficiency. It was demonstrated by the American Committee for the Study of Industrial Fatigue that in the last few hours of extra work there was practically no output. The hours of labor must be adjusted according to the fatigue curve and fatigue limits of the various occupations. The adjustment must likewise be made in accordance with the individual tendencies of the workers. There is the important factor of neuromuscular rhythm which enters into the working capacity of the individual and a group rhythm in the workers as a body. Disturbing elements in this group rhythm reduce the efficiency of the work. It is found that if those having the same rhythm are put together, and those of other rhythms and speeds weeded out of a rhythm group work pro-

ceeds with less fatigue and greater efficiency. When those whose rate of speed is the same are put together it eliminates the tendency to over-speeding of those who have not the same rate of speed. In this way neither the work nor the worker suffers. (Public Health Reports, Jan. 11, 1918).

In keeping with these principles the great war contracts let out could be carried out with the principles of industrial physiology and industrial hygiene clearly in view and enforced to the extent that the knowledge of these subjects is well established. Because of the vastness of the work there is presented a wonderful opportunity to study this subject more in detail, with expectations of substantial improvements to remain with us after the conflict.

RURAL HEALTH NEEDS.

MANY of the notions concerning the superior physical condition, health, and longevity of the rural inhabitant are disappearing under the influence of intensive investigation of rural conditions. The morbidity and the mortality of rural communities are higher than those of urban life. Indeed, these factors are in inverse proportion to the size of a community. Death rate is lowest in the largest communities and highest in the smallest. Whatever benefit there is obtained in the country by the sick or poorly developed city inhabitant is due in large part to the change in mode of living and to the fact that he brings to the advantages of open-air life the sanitary and health notions of the city, the need for which is especially impressed upon him because of his condition. Unless he can live properly and protect himself against the disadvantages of country life he is likely to be harmed rather than benefited. It is found that the general physical condition of the rural inhabitant is far below that of the city (Public Health Reports, Reprint No. 366). This is particularly true of children. The facts that rural communities do not receive the benefits of adequate health supervision and cannot have the advantages of the expert medical care of the city are probably the most important elements in this problem. The rural school child represents about 60 per cent. of the total school population and yet receives a minimum amount of medical supervision. The school medical inspection is but poorly developed in most States. The physical condition and the vital resistance of the school child in rural communities is much lowered by the presence of such endemic diseases as malaria, hookworm, pellagra, etc. Adverse school conditions with respect to light, heat, ventilation, and other facilities increase the defect incidence of these children and still further lowers their resistance to infection.

Only in the larger cities does the school curriculum include systematic physical exercise, so necessary to physical development. Measurements

of rural school children have shown almost uniformly that the rural child falls below that of the city. Weight deficiencies in both sexes vary from 2 to 8 per cent. Despite the fact that the country is the source of the food supply, the rural inhabitants do not receive the benefit of the best. That goes to the market. Carbohydrates seem to be the main food element. The rural child gets very little protein. Many of the carbohydrates contain little vitamine, whereas such foods as milk, eggs, meat, etc., contain much of the food vitamins, but they are comparatively expensive. On the other hand, much of the bad food balancing is due to ignorance of food values rather than to deficiencies in the supply. In the winter months in the northern climates rural inhabitants get very little into the open, and their diet, aside from vitamine-deficient carbohydrates, consists of preserved foods. Of course, very little fresh food is consumed.

The presence of so large a number of physical defects among the rural population is due mainly to the lack of facilities for their correction. The correction of visual defects, hearing, teeth, orthopedic conditions are all sadly needed in these communities. Communicable diseases are common and uncontrolled in most rural communities. The New York State Department of Health is recognizing these needs and is establishing sanitary supervisory districts throughout the State. The school systems are receiving attention. And where children need treatment the same is indicated. Propaganda work along health lines—the care of the teeth, food, air, etc., is carried out in each district. The establishment of a system of rural district nursing on an adequate scale would not only give rural inhabitants the benefit of scientific nursing during sickness, but would be a potent means of controlling and of keeping track of communicable diseases.

THE TREATMENT OF INFECTED WOUNDS.

THE subject of infected wounds and the treatment thereof has been discussed frequently and at considerable length during the past three and a half years, and no absolute consensus of opinion has been arrived at with regard to the most effective manner of dealing with them. It is assuredly agreed by all surgeons who have had experience in the war that an infected wound should be freely drained, and, with this end in view, excised and incised in the most thorough and extensive way whenever necessary. Free drainage is now acknowledged to be the most important part of the procedure, without which all other measures will be futile. As for the use of antiseptics, opinions diverge somewhat widely. There are those who can recognize no value whatever in them, while others, who are in the majority, hold that they have a definite place in the treatment of septic wounds.

Major G. W. Crile, in *Surgery, Gynecology and Obstetrics*, for April, 1918, puts the matter in a

nutshell when he says that no chemical antiseptic can command good results with bad surgery; good surgery commands good results without chemical antiseptics, but the best results are the sum of good surgery and the proper use of good antiseptics. In short, under the conditions of modern warfare, the antiseptic treatment of contaminated wounds is frequently indicated. According to Crile, if antiseptics are required, the choice at present would be between the Carrel-Dakin solution, "bipp" (a paste of bismuth, iodoform, and paraffin), dichloramine-T, and flavine. Going more closely into details, an open, fairly superficial wound, without inaccessible areas, does admirably with physiological saline solution, which, by the way, is, of course, not an antiseptic, Carrel-Dakin solution, bipp, or the electric light, perhaps best of all by the last named. A wound with deep injured areas will do well if treated by the Carrel-Dakin method or bipp. In the period of acute infection, if conditions permit, the best single treatment undoubtedly is by hot packs; in time of stress, bipp; in deep wounds, dependent drainage; in quiet times, Carrel-Dakin. When the wounded come in waves, and surgeons and nurses are swamped, incision and bipp give the best results to the greatest number per surgeon. But the paste must be spread on thinly, not applied in masses, and the wound should not be sutured, but should be lightly packed.

In the *International Journal of Surgery* for February, 1918, Mr. Rutherford Morison contributed a paper on the treatment of infected suppurating war wounds, in which he describes the composition of bipp and the correct mode of using it. Attention is especially drawn to the point that while the whole wound should be filled with paste, all excess should be removed, leaving only a thin covering over the wounded surface. A certain amount of prejudice is felt against bipp on account of the danger of poisoning from bismuth and iodoform. Morison says his own experience has taught that in the early days, when the preparation was used for filling wounds, with no regard to the quantity retained, occasionally symptoms of serious absorption followed. When, however, care is taken to have the paste made properly, and to remove all excess after rubbing the paste well into the wound surfaces, there is little or no fear of serious absorption. He holds that in the treatment of infected, suppurating wounds, bipp takes high rank, and that it is equal to the Carrel-Dakin method in some cases, and perhaps superior in other cases. It possesses the inestimable advantage, so far as war surgery is concerned, of not requiring the somewhat elaborate and careful technique which is essential to the success of the Carrel method.

MORBIDITY STATISTICS OF WAR INDUSTRIES.

ACCURATE morbidity statistics are essential if disease is to be effectually prevented. It is impossible to prevent or control disease if it is not known

where and under what conditions cases of disease are occurring. Drs. B. S. Warren and Edgar Sydenstricker, U. S. Public Health Service, in Public Health Reports, February, 1, 1918, state that morbidity statistics, as an index to a population's health, are regarded without question as one of the most needed instruments and one of the most desired goals of preventive medicine. Moreover, the matter is of supreme importance at the present time. Although it is necessary that labor should put forth every ounce of strength, it is mistaken policy to overexert to the point of fatigue. It has been definitely shown in Great Britain that the adequate recording of sickness is fundamentally necessary to intelligent steps for the prevention of lessened efficiency in war industries. In Great Britain the spur of necessity has brought about reforms as to the collection and tabulation of morbidity statistics that in time of peace would have taken years to achieve. Warren and Sydenstricker therefore think that this country should take a lesson from England and proceed forthwith to set its house in order in this respect.

They tentatively make the following suggestions:

- (1) Exposure, in years or in months, of the workers who should be classifiable according to sex, age, and occupation.
- (2) Cases of sickness, at least those causing disability, including (a) sex, age, and occupation of persons affected and (b) cause of sickness with time of onset, length of disability, and nature of termination.

The above are the minimum requirements for a maximum volume of data and it is believed that their collection is practicable within certain bounds for the following reasons: (1) A large number of industrial and transporting establishments are already in the habit of recording disabling cases of sickness, and a considerable number of the larger establishments employ industrial physicians and provide medical service. The tendency is unmistakably toward an extension of sick benefit funds and of medical supervision and service. (2) There is a very evident willingness on the part of many employers as well as on the part of many organizations of labor and associations for sick benefits to cooperate in every way possible with the public health agencies. The willingness was clearly manifested before the outbreak of the war and has been undoubtedly increased since the war began. (3) There already exists, therefore, a basis for an important beginning in the recording of morbidity. It is believed practicable to utilize the facilities that already are available, provided (a) that the recording of exposure and incidence be extended to all the employees of each plant, (b) that uniformity be established in the form of the medical certificate and in the records of age, sex, and occupation of the persons exposed and affected, (c) that regularity of reporting be effected, and (d) that there be a responsible central supervising, assembling, and publishing agency for the statistics recorded.

The cooperation of large establishments is necessary to make such a scheme a complete success. If

only, however, a few large establishments would cooperate with this end in view, there is little doubt that many would follow and that ere long the systematic collection and analysis of morbidity statistics not only for the "war industries" but for other industries as well would rapidly develop.

TWO HEALTH COMMISSIONERS.

DR. AMSTER, in refusing to be the tool of Mayor Hylan in his attempted disruption of the Health Department of New York City, is to be congratulated. His resignation does him honor, and reflects credit upon the profession of which he is a member. His faith in the good intentions of the Mayor must have been very strong, for it stood a good many severe bumps before being shaken; but at last it went, and then Dr. Amster did what any honorable man would of necessity do, and thereby preserved his self-respect and earned the commendation of his colleagues. The acceptance of the commissionership by Dr. Copeland is most puzzling. The new commissioner was literally—according to his own account—picked up in the street and plumped into the health officer's vacant chair. What is one to think of the Mayor who would take the first physician that crossed his path after Dr. Amster had resigned and put him in charge of the health of the city? Dr. Copeland happens to be a man of education and intelligence, who stands high in the community and in his profession, but suppose Mr. Hylan had met a man of the Old Doctor Grindle type! Dr. Copeland announces that the Mayor has promised him a free hand, and that if interfered with he will resign at once. Unless the Mayor is more alarmed than he affected to be when he told Dr. Amster he didn't "give a darn for those federal government letters," or unless Dr. Copeland likes his new job so well that he is willing to sacrifice something to keep it, we shall look for his resignation before the week is ended. We believe the Governor of the State has the power and the duty to remove a Mayor guilty of malfeasance, and we wonder if he will ever have occasion to do so.

ALOE AS A VULNERARY AND IN POISONED WOUNDS.

KNOWLEDGE of the therapeutic powers of humble remedies is always abandoned as soon as better and more available substitutes appear. Pugno of Geneva illustrates the universality of this law in a short contribution to the *Journal de médecine et de chirurgie pratiques* for March 25, in which he outlines some old and new local uses of powdered aloes. Galen acclaimed the drug as a vulnerary, and stated that it could close fistulae and was of especial value in ulceration about the genitals and anus. In the Middle Ages it had a reputation as a desiccant and stimulant of granulations, and it is so used even to-day in veterinary practice and among primitive peoples. In his visit to the Antilles, Laney saw the fresh juice used as a vulnerary. In seeking to verify these claims the author first tested the drug in the stings of wasps and mosquitos. On account of the great prevalence of the latter in the French Oriental army, a saturated solution of aloes in alcohol was tested with

extremely satisfactory results. The simple tincture naturally also proved of value. It was necessary, however, to rub these preparations into the skin as soon as the bite was received. Severe stings by bees, wasps, and hornets responded so promptly to this treatment that tincture of aloes should be kept on hand for such accidents. A further research into literature shows that the medieval "Baume du Commandeur," which contained aloes, was warmly recommended as a dressing for ulcers of all kinds, even chancres and cancers, and for venomous wounds, even those made by the mad dog. Thus far the author is unable to suggest any theory for such activities. He suggests a trial of aloes in snake bites.

DOUBLE SIMULTANEOUS EXTRAUTERINE PREGNANCY.

BILATERAL synchronous ectopic gestation is very rare. A dozen years ago not over seven cases were known in literature, and it is unlikely that this number has been much augmented. Gómez de Rosas of Havana has recently reported a personal case in the *Revista Medica Cubana* for February. The woman was a white multipara, age 34; previous pregnancies normal, not pregnant for 5 years, menses irregular during this interval. Some periods lasted 8 or 9 days, with much blood loss. In September last she missed a period, and had pain in the lower abdomen, with nausea. The medical attendant made a diagnosis of ruptured tubal pregnancy or pelvic hemocele. The author, called in consultation, verified the diagnosis, and the patient was laparotomized in a hospital. The abdomen contained much blood, which came from a rupture in the left tube. The latter contained the remains of a tubal abortion. The right tube, upon examination, was found the seat of a swelling, with thin wall, and was adherent to the ovary. Opened, it was found to contain blood and circumscribed villi. The embryos were not over two weeks old, and appeared to be of the same age. Both adnexæ were extirpated, drainage being through the wound. Bilateral tubal pregnancy is by no means rare, but perfectly synchronous cases are so infrequent that the most careful documentation is required to establish their genuineness. It is to be hoped that this case will be republished in greater detail and with illustrations, including microscopic sections; else, despite its apparent genuineness, it will probably be placed among questionable examples.

News of the Week.

The Assault on the New York City Health Department.—Public hearings have been held during the past week on the advisability of abolishing the Bureau of Public Health Education of the Department of Health. Many physicians prominent in public health work in the United States and Canada have written letters to Mayor Hylan protesting against this course and expressing the opinion that the work done by the bureau is an absolutely indispensable part of public health work. Among those who have protested against the disintegration of the present Health Department are Drs. William H.

Welch, President of the State Department of Health of Maryland; W. A. Evans, former Health Commissioner of Chicago; Charles J. Hastings of Toronto, Canada, President of the American Public Health Association; Peter H. Bryce, Chief Medical Officer, Department of the Interior, Ottawa, Canada; C.-E. A. Winslow, Professor of Public Health at the Yale University Medical School, and Charles V. Chapin, Superintendent of Health of Providence, R. I. Surgeon-General Gorgas in a letter to Mayor Hylan says: "The general tendency in large municipalities is to have men specially trained in sanitation and public health matters. The day has passed when inferior men can do the work and men skilled in sanitation and public health are necessary." Surgeon-General Rupert Blue telegraphed him that "In the larger centers and industrial communities health problems in their relation to industries have never constituted a more important consideration than in these days when increased production along many lines is absolutely essential. The conservation of health, not only among the fighting forces, but in the entire civil population as well, is a wartime problem of the greatest moment." In reply to these protests the mayor is reported as saying: "I don't give a darn for those Federal government letters, or from other people interested in public health education. As long as I am Mayor of the city of New York the Health Department will be run as I see fit." James E. McBride, President of the Municipal Civil Service Commission, has made public recommendations alleged to have been submitted by Dr. S. Josephine Baker which would reduce the cost of administration of the Bureau of Child Hygiene by \$105,000 a year. Dr. Baker published a statement subsequently declaring that a portion of her report had been suppressed and that she did not propose a plan whereby the work of the Bureau of Child Hygiene could be curtailed. Instead of recommending cuts, Dr. Baker said: "As far as I am personally or officially concerned I cannot consistently recommend that any lines of effort now carried on by the Bureau of Child Hygiene be abandoned. I feel that the present condition of the world and the insistence of the Government of this and other countries that child life must be conserved is a matter second in importance only to the actual fighting; this places us in a position where retrenchments which would tend to break down the standards safeguarding children would not be an economy, but a serious detriment to the welfare of the country." The Merchants' Association has written to Mayor Hylan asking him to refrain from making wholesale changes in the Health Department because it would disorganize machinery intimately affecting the health of the entire city. Dr. Amster has resigned as Commissioner, giving as his reason the intolerable interference of the Mayor with his work. Among other things the Mayor demanded the dismissal of Dr. Jacobi from the advisory council because his son-in-law did not support Mr. Hylan, and that of Dr. Goldwater on the ground that he was a "high-brow." Soon after Dr. Amster resigned the Mayor met Dr. R. S. Copeland, a homeopathic physician, on the street

and at once appointed him Health Commissioner of the city.

Hospital Closed.—Following a special conference of the State Board of Charities a recommendation was made that the Williamsburg Hospital, at Bedford and Third Streets, Williamsburg, be closed. This recommendation was prompted by the alleged dangerous condition of the antiquated hospital building. There were sixty-five patients in the institution which were transferred to other hospitals, most of them being taken to the Eastern District Hospital, with which the Williamsburg hospital was consolidated about a year ago.

Health Poster Competition for High School Students.—The Tuberculosis Committee of the Charity Organization Society of New York City, through the cooperation of the Art Department of the high schools and the Department of Health has asked each high school in the city to hold a poster competition, the object of which is to teach the public the most effective way of preventing the spread of pneumonia, tuberculosis, and other respiratory diseases. The best poster is to receive a prize of \$5 in gold. Other prize posters will receive recognition in the shape of medals.

National Association Changes Name.—The National Tuberculosis Association is to be the newly incorporated successor of the National Association for the Study and Prevention of Tuberculosis. Beginning with May 1 the new address of the Association will be 381 Fourth Avenue, New York City. The Fourteenth Annual Meeting of the National Tuberculosis Association will be held in Boston, Mass., on June 6, 7, and 8, 1918, under the presidency of Dr. Charles L. Minor of Asheville, N. C.

The American Association for Promoting Hygiene and Public Baths, of which Dr. Simon Baruch of New York is president, will hold its annual meeting at the City Hall, Newark, N. J., on May 14 and 15. The president's address will be delivered at the Treat Hotel, where a reception will be given by the City of Newark to the members of the Association.

American Proctologic Society.—Dr. Collier F. Martin, secretary, writes that, owing to conditions brought about by the present war, the American Proctologic Society has decided not to hold its meeting in Chicago on June 10 and 11. The society will probably not meet again until after the war is over.

Medical Society Elections.—THE LOUISIANA STATE MEDICAL ASSOCIATION, which met in New Orleans on April 16 and 17, elected the following officers for the ensuing year: *President*, Dr. W. H. Knolle of New Orleans; *First Vice-President*, Dr. G. M. C. Stafford of Alexandria; *Second Vice-President*, Dr. Amedee Granger of New Orleans; *Third Vice-President*, Dr. A. E. Fossier of New Orleans; *Secretary and Treasurer*, Dr. Paul G. Talbot of New Orleans.

THE TOLLAND COUNTY, CONN., MEDICAL ASSOCIATION, at its annual meeting in Rockville, on April 16, elected the following officers: *President*, Dr. William L. Higgins of Coventry; *Vice-President*, Dr. A. L. Hurd of Somers; *Secretary and Treasurer*, Dr. F. W. Walsh of Rockville; *Councilor*, Dr. Thomas F. Rockwell of Rockville.

The Tuberculosis Death Rate in American

Cities.—Chicago stands second in the list of the ten principal cities of the United States having the lowest number of deaths from tuberculosis in 1917, according to a bulletin recently issued by the Health Department of that city. The first in the list is Pittsburgh, with 147.05 per 100,000 population, as compared to Chicago's 148.67 per 100,000. Other cities in the list are: Detroit, 160.06; Boston, 170.87; Cleveland, 174.7; New York, 176.75; Philadelphia, 194.81; Los Angeles, 199.42; St. Louis, 202.95, and Baltimore, 236.61.

Opposition to the Narcotic Bill.—At a hearing last week on the new narcotic bill a number of physicians were present and voiced their objections to the measure. The bill has a number of bad features and it is most desirable that it should not be allowed by the Governor to become a law.

Dispensary Physicians Wanted.—The Public Health Committee of the New York Academy of Medicine reports that the withdrawal of physicians from civil life into military service has created a shortage of men in the dispensaries of this city, resulting in a curtailment of the services of these institutions. When subsequent calls are made upon the medical profession the dispensary service will be still further decreased unless steps are taken to provide for substitutes in this important branch of organized medicine. The committee suggests that an appeal be issued to the physicians who have had dispensary experience but who, at present, have no hospital or dispensary affiliations and who, because of age or for other reasons, are not available for military service, to volunteer for dispensary duties as their contribution to the war.

Annual Report of Beth Israel Hospital.—The twenty-eighth annual meeting of the Beth Israel Hospital Association was held on April 22, when it was announced that a part of the hospital facilities are being used by the Government. More than 116,000 patients were treated last year in the hospital and dispensary. The building fund for the proposed new hospital for which a site has been purchased on Livingston Place has reached \$207,976. A number of the Beth Israel Hospital physicians are in the Government service. Dr. S. J. Kopezky, Dr. Charles Goodman, and Dr. L. B. Meyer are now serving in France.

Plan to Enlarge Volunteer Hospital.—The unusual demands made on the Volunteer Hospital, New York, because the Hudson Street Hospital in the same part of Manhattan has withdrawn its ambulance service and is caring for soldiers and sailors, has decided the trustees of the Volunteer Hospital to add three stories and a solarium to the hospital building. Work will be begun this summer despite the fact that funds have not yet been collected.

Obituary Notes.—Dr. WILLIAM ALEXANDER EWING died suddenly at his home in New York, on April 20, aged 75 years. He was born in Michigan Aug. 20, 1842, and was a graduate of Bellevue Hospital Medical College in 1869. He was a member of the Medical Societies of the State and County of New York, the American Medical Association, and the New York Academy of Medicine. Dr. Ewing was Sanitary Superintendent of the New York City Health Department from 1887 to 1893.

Dr. EDWIN P. RUCKER of Richmond, Va., died of complications following a fracture of his hip several months ago, on April 9, aged 65 years. He was graduated from the Louisville Medical College, Louisville, Ky., in 1877. He was city physician of South Richmond for a number of years and prior to his injury served as medical examiner on a local board.

Dr. AUGUSTUS C. WALKER, formerly of Greenfield, Mass., died at the home of his son in Cambridge, on April 5, aged 84 years. He was a graduate of Dartmouth Medical College, in 1862, served as a surgeon in the Civil War, as Vice-president of the Massachusetts Medical Society, and was for thirty years jail physician of Franklin County.

Dr. CHARLES BOWMAN STURTEVANT of Manchester, N. H., a graduate of Dartmouth Medical College, in 1874, died of arteriosclerosis, on April 12, aged 68 years. He was a collector of rare books and had assembled one of the finest libraries in the State of New Hampshire.

Dr. JAMES THURSTON MARTIN, a graduate of the University of Michigan, in 1883, died at his home in Sacramento, Cal., on March 30, aged 69 years.

Dr. VANDYCK M'KELVEY, a City Police Surgeon of Denver, Col., died of pneumonia, on April 4, aged 31 years. He was a graduate of the Denver University Medical School, in 1910.

Dr. ISADOR SAMUEL LEOPOLD BERMAN died of angina pectoris at his home in Washington, D. C., on April 5, aged 73 years. He was a graduate of the University of Wurzburg, in 1878. He enlisted in the American Army in 1865 and served for three years in the Twelfth Infantry in the Indian campaigns.

Dr. EZRA PRAY, a practitioner of Rochester, N. H., for fifty years, died on April 4, aged 86 years. He served as a surgeon in the Navy during the Civil War.

Dr. T. J. DEEM, a graduate of the Columbus Medical College, Columbus, Ohio, died suddenly of heart disease, on April 3, aged 50 years.

Dr. WILLIAM ARTHUR MOORE died at his home in Binghamton, N. Y., on April 26, aged 50 years. He was graduated from the College of Physicians and Surgeons, New York, in 1885. In 1887 he was appointed surgeon of the Moore-Overton Hospital at Binghamton. He was surgeon for the Delaware, Lackawanna & Western Railroad, the Binghamton Traction Company, and the Delaware & Hudson Railroad. He was a Fellow of the American College of Surgeons and of the American Medical Association and a member of the American Academy of Medicine.

Dr. DANIEL U. WADSWORTH of Tulsa, Okla., died of Bright's disease at his home, on April 13, aged 44 years. He was a graduate of the University of the South Medical Department, Sewanee, Tenn., in 1898, and for some years chief health officer of Tulsa.

Dr. JULIUS A. WINTER, a graduate of the Long Island College Hospital, in 1888, and a physician of the Panama Steamship Company, died at his home in Brooklyn, N. Y., on April 23.

Dr. WILLARD A. LONG, a graduate of Cooper Medical College, San Francisco, in 1882, died at his home in Lewistown, Mont., on April 11, aged 68 years.

OUR LONDON LETTER.

(From Our Own Correspondent.)

CONVALESCENT HOMES FOR NEURASTHENIC CASES—
THE CENTRAL MIDWIVES' BOARD—SMALLPOX IN
LONDON—INCREASE OF JUVENILE CRIME—DRIED
MILK.

LONDON, April 4, 1918.

THE Minister of Pensions, Mr. John Hodge, is finding himself in considerable opposition to the best medical opinions in the attitude which he has taken up with regard to the Homes of Recovery which are being instituted for neurasthenic and shell shock cases. Mr. Hodge has official medical opinion to rely upon, but either this opinion is not as well informed as it should be or he is preferring to listen to the popular view. The popular view is that the neurasthenic patient requires cheering up by intermixture with other patients, and also that as his condition can often be attributed to what is vaguely labeled "shellshock," it is particularly important that the institution into which he is received should be outside the area of possible or probable air raids. Of course, no patients ought to be placed within a danger zone if it is possible to accommodate them outside. But there has obviously been great exaggeration of the ill effects displayed by the shell-shocked patients after subjection to an air raid. So far from being more agitated than any other members of the population, when judiciously handled they bear the ordeal with perfect calm. A limited number of neurasthenic cases may improve when mixed up with a general hospital population. Some also may only require ordinary treatment in a convalescent home, or can be boarded out as country visitors, or may be added to the population of village centers, but as a rule those suffering from functional nervous disorders require special treatment which can only be given in special institutions. The scattering of neurasthenic patients in various directions on the chance that a proportion of them may get better is a policy directly opposed to that intensive treatment of disease which has proved in every department of surgery and medicine to be the really efficient way of dealing with the pathological results of the war. The War Office has taken a better line than Mr. Hodge, in the opinion of real neurologists, when the military authorities issued a recommendation that all soldiers suffering from a functional nervous disorder should be segregated for treatment into special hospitals immediately on their home arrival, and that such hospitals should be staffed by medical officers interested in, and specially trained for, the work. There is a strong feeling in medical circles that the Ministry of Pensions should be provided with some sort of advisory medical council so that the minister might be kept in better touch with scientific medicine. Undoubtedly it is a popular belief that it does the neurasthenic patient good to be cheered up by the merry convalescents from minor surgical injuries, but official support of this belief may produce feelings of considerable anxiety among the relatives of neurasthenic patients who are receiving the proper treatment of intelligent segregation and individual scientific attention.

This board stands in similar relation to quali-

fied midwives to that of the General Medical Council in relation to qualified medical men, that is to say, it standardizes the education of midwives who practise on a legal register under the Midwives Act, and it supervises their professional conduct, removing from that register those who infringe the instructions of the Act, or whose conduct in other ways is dangerous to the public or degrading to their class. The chairman of the board is Sir Francis Champneys, formerly obstetric physician to St. George's Hospital and St. Bartholomew's Hospital, and now consulting obstetrician to the latter institution; and the work of the board is far from light. When the Midwives' Act came into being a certain number of the old unlicensed midwives were placed upon the statutory roll in recognition of past practice, their vested interests being supported by testimonials from medical men who had worked with them over a period of years. Many of these women, and some of the midwives who have been placed on the roll after due examination, are constantly proving themselves untrustworthy and being struck off the register, a position which is rendered awkward by the fact that the salaries attached to midwifery practice for a midwife under the Act are not tempting. A shortage of midwives is therefore expected.

A rather widespread epidemic of smallpox invaded six of the metropolitan divisions of London during February and March, not being recognized until the latter month. Owing to the long period before the presence of the disease was detected in the community it seems fortunate that the number of cases, at any rate up till the early part of April, should have been so small. The six metropolitan boroughs invaded, namely, East Ham, Stepney, Hackney, Bethnal Green, Poplar, Deptford, and Lambeth, are five of them contiguous, but Deptford and Lambeth are on the south side of the River Thames, and Lambeth, though in commercial communication with Deptford, does not actually touch it. The population in all these boroughs, which lie along the shores of the Thames and its tributary, the River Lea, is industrial, and especially where the boroughs border on the docks are the chosen homes of the alien population. The sanitary condition of many of these aliens is necessarily very rudimentary. They arrived from anywhere, knowing nothing, and as far as possible lead a nomad life in their new environment. The history of the outbreak is somewhat interesting, while the origin remains unknown. The epidemic first appeared in Stepney, where on February 13 a child died of pneumonia, whose body, it was later learned, presented the appearance of an attack of smallpox. By the beginning of March several cases were notified and by the beginning of April the distribution of the disease in London was, Stepney, twenty-two cases; Hackney, three cases; one each in Poplar, Deptford, and Lambeth, and three in East Ham. The particular attention of the authorities has been directed to the conditions of the shelters provided for the congregation of populations during air-raids. The densely crowded situations of the docks have on the whole been attacked from the air more frequently than other parts of London, and their populations, the aliens in particular, are ready to seek shelter on the

slightest provocation. The authorities therefore, besides taking all the necessary steps to ascertain the sources of infection and to vaccinate the contacts, are paying particular attention to the sanitary conditions of air-raid shelters. There has been no epidemic of smallpox in London of anything like a serious nature for fifteen or sixteen years, although some seven years ago there was a small outbreak in the west of London. The unvaccinated condition of a large proportion of the child population is necessarily causing anxiety.

Terrific figures pointing to the increase of juvenile crime have reached this country from Germany. The Hessian Minister of Justice has confessed in the Diet of Darmstadt that the effect upon German morality of the war is increased by the outburst of crime among the quite young. Sentences have been passed in Hesse upon young criminals in the following comparative numbers: 285 in 1915; 347 in 1916, and 468 in 1917, the total population of Darmstadt being under 90,000. The total convictions of children for minor offences was 1,145 in 1915; 2,895 in 1916, and 4,012 in 1917. Unfortunately England cannot say Pharasaiically, "Thank God, we are not as the Germans," for with the outbreak of war there was a distinct increase of juvenile ruffianism, owing to the absence of male parents at the war, the occupation of many female parents in auxiliary war work, the relaxation of school discipline through shortage of teachers, and the opportunity for mischief given by the darkened streets. Gloomy psychologists, nearly always medical men, have prophesied a serious sequel to this condition of things, but the ready return to the normal which has followed everywhere upon intelligent punishment puts their forebodings to rout.

From a medical point of view milk has become a very valuable commodity to our population. I have referred recently to the careful manner in which it has been rationed with a special eye to the needs of pregnant women, nursing mothers and infants, and owing to these timely measures and the possibility of obtaining by medical certificates extra milk for certain categories of invalids, no grave hardships have been endured by the weaker sections of the community; but the man power of the country is so closely engaged in the conduct of the war that the transport of milk in its natural form and the storage and distribution as a fluid present real difficulty. In recognition of this fact the local Government Board have issued a report made to them by one of their most experienced officers, Dr. F. J. H. Coutts, on the use of dried milk, with especial reference to infant feeding. Dr. Coutts divides dried milk, as put on sale in England and Wales, into four classes in the following category: (1) Full cream; (2) Three-quarter cream; (3) Half cream; and (4) skim milk, adding that it is most important, despite these varieties of choice, that infants should, whenever possible, be fed solely on their mother's milk. When, however, this is impossible, says the report, there is good evidence that cow's milk in dried form will prove a satisfactory substitute, while if properly done the cream can be thus retained. Dried milk has already been largely employed in connection with infant welfare centers in England, particularly in Leicester and Sheffield, and experi-

ence in these towns, and in other centers, shows that a large proportion of babies can take dried milk very well, and that on this food they thrive and develop in a very satisfactory manner, digesting the "reconstituted" fluid well, and even vomiting less under its use than when fed on ordinary cow's milk. The convenience of using dried milk, when its position as a good food is safely established, is obvious. When carefully prepared from good fresh milk it will keep in a dry place for months. On mixing with warm water in the proportion of one part by weight of the dry powder to seven parts by weight of water a liquid is obtained corresponding in composition to ordinary milk in every physiological way, as far as tests can show, and then whether the powder is obtained by spraying fresh milk, after partial condensation, into heated air, or by the older process of passing the liquid over cylinders heated internally by steam. The former is the preferable technique. The difficulties surmounted by the use of dried milk are enormous, for seven-eighths of the weight for carriage is abolished, which, the perishable fluid being removed, storage, within reasonable limits, becomes easy. Dr. Coutts' report will lead to a great use of dried milk in infant welfare centers and elsewhere.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

OUR SACRED DEAD—NEW ALLIED MEDICAL LIBRARY—RESEARCH WORK.

PARIS, March 11, 1918

DAWN lifted on No Man's Land somewhere in France. From the observation post in a front-line trench it was reported that the bodies of two American soldiers were lying between the German and the British lines. A detachment of engineers had been in action for the first time a few days previous. For days they lay there. English soldiers and Germans lay on the same field. It was impossible to reach them. The Hun's shells were still ploughing up great furrows of earth and the bullets from his small guns made it unwise to attempt to recover the bodies. Each morning as the light of day came the observers reported that the bodies were still there.

Then one night in the darkness a party of Tommies left the trenches. They carried spades instead of guns. It was a burial party and was in charge of a chaplain. When the following morning came the bodies of the two Americans were gone. A nearby shell hole had been filled up, and on the top of it two white crosses marked the graves of the first Americans who had been buried in No Man's Land, where they had fallen fighting shoulder to shoulder with their British cousins, for their convictions and their country's honor.

The military medical and surgical division of the American Red Cross has taken over the Rheinhardt Galleries, 12 place Vendôme, and has converted them into a library, study-rooms, and reception hall for physicians and surgeons of all the Allied Armies. These new quarters were donated to the American Red Cross by Mr. Rheinhardt. One of the principal features will be a register which will enable all of those visiting to get in touch with

others of their profession whom they are desirous of meeting. The library will be equipped with some 1500 medical volumes, and all the magazines devoted to matters of interest to the medical profession will be on file.

Beginning on Friday, February 15, the Research Society of the American Red Cross will begin its monthly meetings in the new quarters. At these meetings some phase of war conditions is debated. The subject of the next discussion will be meningitis.

Major Alexander Lambert, M.O.R.C., U. S. A., director of the military medical and surgical division of the American Red Cross and chairman of the medical advisory committee of the department of military affairs, together with his staff, has made arrangements for the occupation of the apartment, which now is completely furnished. The medical division will have charge of the rooms.

A prominent medical official of the American Red Cross stated that the Allied medical profession has generously put at the disposal of the American Army the results of its three years' study of the war conditions and surgery. The treatment of wounds and surgery in general have very much altered during the last two years.

Research work is being conducted by American doctors in conjunction with British colleagues on the English front, where they are studying the cause and effects of trench fever, which affects from eight to ten per cent. of the Army. Although this sickness is not fatal, it renders the men useless from a military point of view, and if an antidote can be found to prevent it there will be a very great saving of man power.

It is hoped that the new apartments taken over by the American Red Cross will be a center for the medical profession of all the Allied armies, and that it will give its guests an opportunity to exchange views and discuss medical questions with one another.

5. **Surgical Prognosis in Gallbladder Disease.**—E. McD. Stanton has made a special study of the end results in 100 consecutive operations performed because of symptoms referable to the biliary tract. In the series the average time that has elapsed since the operation is three years and eleven months. At the time of operation, gallstones were present in seventy-two patients. Of the remaining twenty-eight, three had cancer involving the biliary tract; one had a benign obstruction of the common duct, and twenty-three were cases of cholecystitis. Three deaths occurred in the series. In regard to the operative mortality in gallbladder surgery, Stanton points out that though Mayo reports an average mortality of 2.75 in 4000 operations, 1051 operations in thirty representative American hospitals during 1908-09 resulted in eighty-seven deaths, or 8.2 per cent.; and the mortality in 131 operations

performed in the Ellis Hospital previous to Jan. 1, 1916, was 8.4 per cent. Mortality rates of 8 per cent. he considers too high, and states that they are due either to poor technique or to bad judgment on the part of the surgeon. The results obtained in this series of cases, together with those published from other sources, have led Stanton to conclude: (1) Provided a low operative mortality can be assumed, the operative treatment of gallstone disease is one of the most satisfactory branches of surgery. (2) There is a decided difference between the results obtained in gallstone cases and in cases of simple cholecystitis without stones, so that the results for the two classes of cases should always be tabulated separately. (3) In gallstone cases if, as a result of the operation, all obstructions within the biliary tract are removed, cure is almost certain to result. Overlooked stones are probably the most important single cause of uncured patients. (4) Cholecystectomy may have certain advantages over cholecystostomy, but cholecystectomy of itself does not protect against the development of common duct stones or obstructions, and in the series here reported a recurrence of typical biliary colics beginning a year or more after the operation has been more frequent after cholecystectomy than after cholecystostomy. (5) In gallstone cases the difference in the end results between cholecystostomy and cholecystectomy is never great enough to warrant attempting a dangerous cholecystectomy if a safe cholecystostomy can be performed. (6) In cholecystitis without stones simple drainage of the gallbladder does not give better results than could probably be secured by medical means. (7) A certain proportion of patients presenting gallbladder symptoms without the presence of stones are cured by cholecystectomy, but disappointments in this field of gallbladder surgery can only be avoided by a very careful selection of cases based on a thorough knowledge of the relation of symptoms and pathology in gallbladder disease.

5. **The Value of Roentgen Rays and Benzene in the Treatment of Polycythemia Vera.**—Samuel H. Hurwitz and Ernest H. Falconer point out that the treatment of polycythemia associated with splenomegaly has not been entirely successful. They review the various methods employed and show that the results obtained by the use of the roentgen rays alone have been contradictory. They have found, however, that the combined use of benzene and roentgen rays has been of benefit, and they give the report of a case which presented the classical signs and symptoms of polycythemia vera, stating that although more than a year has elapsed since any form of treatment was given, the patient's blood still shows a normal number of red corpuscles and a normal hemoglobin percentage, and that her health continues excellent. This patient only received 44 grams of benzene within a period of a month, after which the administration of the drug was discontinued on account of nausea, gastric discomfort, and headaches. The roentgen ray treatments were continued for about two months longer. Considerable reduction in the red count followed the use of the benzene alone, but it was only after the seventh roentgen ray treatment that the erythrocytes began to approach the normal level. Commenting upon the results obtained in this case, these authors refer to the fact that it has been shown by experimental and clinical observations that various drugs and radioactive substances exert a selective action on the tissues which give origin to the formed elements of the blood, and that the leucopoietic

tissues are less resistant to their destructive action than are tissues concerned with the formation of erythrocytes. Roentgen rays exert a selective action on the lymphocytes, whereas benzene acts destructively on the white cells and more especially on the nongranular elements, and later causes a diminution in the number of erythrocytes. This drug, however, in order to effect any striking anemia, must be given in large doses and over a long period. It is because of this essential lymphotoxic action that the roentgen rays alone have not proved to be of great value in the treatment of polycythemia. Benzene, on the other hand, has yielded some brilliant results, but it must be remembered that the prolonged ingestion of large doses of the drug may be followed by severe gastrointestinal disturbance and a marked destruction of the circulatory leucocytes. The treatment given in the case reported was instituted in the hope of testing the value of smaller amounts of benzene combined with the roentgen rays, and the good effects of the treatment may be attributed either to the joint action of both measures or to the cumulative action of the benzene itself. It is significant, however, that previous observers did not succeed in appreciably reducing the red count with the same amount of benzene. The authors, therefore, attributed the success in the case reported to the combined action of these agents, but state that the manner in which the roentgen rays may have served as an adjuvant to benzene therapy is not clear. They suggest that these rays may act in a more destructive manner on erythropoietic tissues, which have been rendered less resistant beforehand by the toxic action of benzene.

6. A Plea for Universal Service. Edred M. Carner.

5. A Preliminary Note on the Trophic Disturbances in Gunshot Injuries of Peripheral Nerves.—John S. B. Stopford, in a report to the Medical Research Committee, points out that the vasomotor, secretory, and trophic disturbances encountered in the study of injuries of the peripheral nerves are very diverse and extremely difficult to understand and that much confusion and delay has been caused by attributing their origin to concomitant vascular implication. He has recently paid particular attention to the condition of the blood vessels and associated state of the skin, muscles, joints, and bones in the field of distribution of all nerve injuries, the points of special interest being the rosy red color of the skin, increased surface temperature, tumefaction, and fairly frequent hyperhidrosis; and, later, glossy skin, trophic sores, and decalcification of the phalanges and metacarpal or metatarsal bones. Deformities in most cases are produced by fibrous retraction and consequent shortening of the muscles, and sometimes by arthritic changes which resemble rheumatoid arthritis, in which nervous factors are of the greatest importance. In a few very late cases Stopford has found gangrenous patches on the sole of the foot or affecting the toes; and although this strongly suggested arterial obstruction, there was no evidence of an arterial lesion at the site of the wound. In all cases there was marked contracture of some or all the muscles supplied by the injured nerve with extreme limitation of passive movement. Examination of a leg amputated from a young man of twenty-three, who had sustained a gunshot wound of the left thigh eighteen months previously, produced evidence of endarteritis localized to the distal part of the limb and increasing in severity toward the periphery. In the absence of syphilitic (the Wassermann test was negative) or other infection, or indication of any local source of inflammatory implication, or direct involvement of the blood vessels, the author

assumes that the vascular changes were secondary to the peripheral nerve lesion, as was suggested by cases which had previously come under his notice. He points out also that the anatomical researches of Todd have shown that the vessels of the limbs are supplied directly from the various nerve trunks and that the nerve supplying any muscular or skin area also supplies the blood vessels of that area. Furthermore, endarteritis has been found in peripheral neuritis and has been experimentally produced by operation upon peripheral nerves in rabbits and dogs. The appearance of gangrene and other features in the late stages of some of Stopford's patients strongly suggested arterial obstruction and the constant fibrous contracture of muscles showed a more serious condition than was to be expected from a simple nerve injury. He emphasizes the point, however, that this contracture was only found to occur in the muscles whose nerve supply had been affected, as was indicated in the case of a patient who received a gunshot wound of the left forearm about the level of the lower limit of antecubital fossa, the only muscle showing contracture being the flexor sublimis digitorum, which was paralyzed. There seems little doubt, therefore, that the muscular contracture is due to ischemia, which is secondary to vascular changes caused by the nerve injury. It is probable also that decalcification of bone may arise from the same cause. Stopford concludes that there is strong reason to suppose that irritative nerve lesions can produce changes in the walls of the arteries supplied by the affected nerves, which changes seriously reduce the caliber of the vessel and diminish the blood supply to the muscles, bones, joints, and skin. He adds: "The practical point of great importance at the present moment is the early relief of the irritation. In this way the arterial changes which produce such serious complications may be prevented."

2. The Tolerance of Physical Exertion as Shown by Soldiers Suffering from So-called "Irritable Heart."—Thomas Lewis contends that the surest means of gauging capacity for physical endurance is to test the men upon drill, the highest grades of which should approach in their severity the tasks which will be set to these men when they return to their depots. He says the test of capacity for work should be the observed reaction to work. This system has been adopted in a large number of military hospitals both in England and abroad. The drills are termed B 15, C 15, BC30, C 30, and D 30, the letter indicating the stiffness of the exercises and the number the duration of the drill in minutes. D 30, for instance, includes many of the stiffest exercises or the army exercise book, and entails thirty minutes' hard work. These exercises are supplemented by marches and outdoor games. Patients on fifteen-minute drills are considered unfit to leave the hospital except under escort, whereas afternoon passes are given freely to men on thirty-minute drill, a rule which stimulates the men to accomplish the thirty-minute drills. Each man is examined once or twice weekly immediately after exercise. The chief complaints of the men as they come from drill are breathlessness, precordial pain, palpitation, giddiness, and fatigue. Objective evidence of symptoms is insisted upon. A changing symptomatology is to be distrusted. The tolerance of exercise must be judged by physical signs and not by symptoms, and the medical officer must always be on guard to detect efforts to exaggerate the signs of distress; on the other hand he must use discrimination in the case of the man who refuses to

complain. He is also warned not to place particular emphasis on any one symptom, as this has been known to lead to an epidemic of that symptom in the service. It has been found that the men work better and more uniformly when left to the drill instructor, and the constant supervision of drill by medical officers has been abandoned. In judging the toleration of prescribed exercise, the *facial expression* must be carefully observed; rapid breathing by itself is scarcely sufficient evidence. In such cases the accessory muscles are called into play, the *alae nasi* are expanded or active, the mouth slightly open, the eyebrows drawn together, and the breathing audible; a slight but distinct duski-ness may develop under or around the eyes, and pallor of the whole face is not unusual. In some cases this altered facial expression is maintained while at rest. When *precordial pain* is complained of after exercise, the chest should be stripped and the hands of the examiner placed outspread symmetrically on the axillary and submammary regions and pressure exerted as though to steady the chest or to bring the patient to a more convenient position. This simple action may be sufficient to disclose hypersensitiveness; in some patients, indeed, the slightest pressure on the left precordial region and a wide surrounding area is resented. In others it was necessary to slip the hands higher, bringing the thumbs over the borders of the pectoral muscles and pressing again, or to proceed further and while *interrogating the patient*, to grasp the pectoral folds with increasing firmness between thumbs or fingers. Where the muscles are sensitive on the left side the patient winces, the left shoulder is depressed, the facial expression alters, or the reply is momentarily interrupted or actually broken off by a movement or expression of protest. When no hypersensitiveness of the left chest wall is detectable after exercise, the plaint of pain may usually be neglected. In extreme cases hyperaesthesia is found beyond the chest area and exists in the skin of the upper arm; not infrequently it also involves the tendons of the sterno-mas-toid muscles. Tenderness of the anterior border of the trapezius muscle suggests a closer examination for signs of early tuberculosis. Patients should not be asked, Is this or that region sensitive? A complaint of palpitation is to be neglected as such, but is serviceable as a guide to persistent or excessive tachycardia. The usual rate of the heart's action while a patient is up and about, and especially after set test exercises, is of much importance. *Giddiness* is a common complaint, but as a prognostic sign has little value. *Fainting* may occur infrequently. The chief form of attack, and one which may always be regarded as genuine, is that accompanied by a feeble and slow heart action (30-50). It may be preceded by a short interval of giddiness, by a sense of weakness or unsteadiness. Consciousness is lost, and the fall is sudden, but rarely heavy. Pallor and sweating are present. Involuntary movements are slight, and usually confined to the face and arms; a general rigidity may be developed; the tongue is not bitten, neither is the urine passed. Nausea or vomiting may be present. The attack lasts from a few seconds to a few minutes, and is followed by lassitude and headache. A history of earlier attacks is common; these are associated usually with emotion (sight of blood, etc.), long standing at attention or the cessation of sudden effort; they do not occur in recumbency. Recovery is always complete, and an attack should not break the routine of drill for more than forty-eight hours. Attacks which are inconsistent with this picture are to be viewed with suspicion unless they may be ascribed to epilepsy. A complaint of *fatigue* or *exhaustion* is rarely unaccompanied by other complaints, and may be disregarded unless often repeated and accompanied by signs, such as pallor, or by uncontrollable tremor of lips or limbs, or by signs of breathlessness, as the grade of exercise is raised. Stiffness of the limbs or trunk muscles, accompanied by tenderness, is experienced by some unpromising cases to an unusual degree as an after-effect of short exercise. Pain in the axillary region, back, or limbs is usually related to a particular action during drill, and as a general rule does not endure.

4. An Essential Principle in the Treatment of Gas Gangrene.—Colonel H. M. W. Gray urges the recognition and application of the principle, which he believes

is essential for the successful prevention and eradication of gas gangrene in war wounds, that whether one undertakes preventive, pre-inflammatory operation, or curative operation after the gangrene has developed, success and safety are assured only when the wounded parts are excised until *definite* bleeding of the cut surface is seen. The bleeding must be definite; it need not be free. He points out that the causative bacilli of gas gangrene will not develop in tissues which are provided with a vigorous circulation and that they thrive best when the circulation is entirely stopped. He states: In pre-inflammatory operations the use of a tourniquet during operation may be permissible; it is not advisable unless the patient is exsanguinate. In cases where gangrene is already well marked it should not be used. Care must be taken that in excising parts at the later stages of the operation the blood supply of tissues left behind at an earlier part of the operation is not interfered with; therefore, as a rule, proximal parts should be excised before distal parts. It is usually easy to decide, when this principle is kept in view, how much should be excised—whether only part of a muscle, the whole muscle, a group of muscles, or the limb.

February 4, 1918.

Plastic Survey of the Face in Wounds of Warfare.—F. Karewski contributes a paper with illustrations and detailed case-reports on this interesting subject. Besides the personal initiative which should be adapted to each particular case, Karewski offers some general principles, namely, not to hesitate to wait for the end of the infectious or necrotic process to take place before undertaking a plastic operation. He points out rightly that it is better to "lose time" than to assume the risks of a complete failure, which would only make matters worse. The plan of the operation can only be made after excision of the cicatrices and mobilization of the wound edges, because it is only then that one can judge of the opportunity of transplantation and its requisite extent. The forehead, temples and cheeks lend themselves to union with covering over of the defects, with suture of the parts. Palpebral and nasal plastics, when they need no bony underlayer for support, should be made with skin flaps taken in these areas. The use of skin flaps with transplantation of pieces of cartilage is an excellent procedure, but must not, however, cause one to neglect preserving the remaining autochthonous cartilage as much as possible in reconstruction of the nose and eyelids. Generally speaking, it is better to multiply the number of operations by employing little by little the remaining tissues rather than to perform a total plastic operation at the onset of treatment. Very extensive wounds of the cheek will admirably adapt themselves to Israel's technique. This consists in taking a large pedunculated flap from the side of the neck and the raw surface resulting can be easily covered and closed with sutures on account of the great mobility and laxity of the integuments covering the neck.

The Reversion of Sexual Inversion by an Exchange of the Sexual Glands.—E. Steinach and R. Lichtenstein offer a study on sexual inversion, a question dear to the Hun medical profession, perhaps because the condition is more prevalent in the Teuton race than in any other people excepting Orientals. The writers recall, in the first place, the rôle of the sexual glands from the endocrine standpoint, such as stimulation of the homologous sexual characters and inhibition of heterologous characters. Their action is directed more particularly to the psychic characteristics, as well as on the somatic ones. It is quite possible to cultivate the sexual glands of both sexes in the same subject, in which case the manifestations of both somatic and psychic hermaphroditism will develop. It therefore happens that human hermaphroditism can be attributed to a mixed internal secretion, although the external secretion is unisexual in character, and such organisms contain "hermaphro-

dite glands." The distinction between true hermaphroditism and the pseudo type consequently is false. These experimental data can be applied clinically to man. Lichtenstein operated on a soldier who had lost his testicles by an exploding shell by implantation of a cryptochide testicle, the result being a return of the sexual characters and result has been maintained for two years and a half. A distinctly sexually inverted subject was grafted in the inguinal canal with a bit of testicle taken from a subject having an ectopic testicle which was removed because of symptoms of violent strangulation. Twelve days after the graft the man showed signs of a change to masculine sexuality. Suggestion was not alone the cause of the change, because the somatic characters of a sexual inversion were replaced by distinctly masculine characteristics. The writers therefore propose an operative treatment for homosexuality.

Gunshot Wounds of the Knee-Joint.—Kreglinger offers the following rules: (1) Conservative treatment in perforating wounds of the knee with carbolyzed camphor. (2) The presence of the missile requires immediate operation for its removal and the use of carbol-camphor if sepsis occurs. (3) Wounds from shrapnel or exploding shell should be opened up and irrigated with carbol-camphor, a 2 per cent. carbolic solution or a physiologic salt solution until the temperature returns to the normal. Immobilization and ultimate treatment is carried out by splints with the limb in semi-flexion; later on a plaster cast is applied.

Deutsche medizinische Wochenschrift.

February 7, 1918.

Modern Theories on Muscular Tonus.—E. T. von Brücke in his article (continued from the previous issue) next considers the part played by the sympathetic nerve in maintaining the tonus of striated muscle. He refers to the contradictory results obtained by different workers by varied methods, and concludes that the rôle of the sympathetic is not proven to a certainty. However, by denervation of the sympathetic the innervation of the muscles is disturbed and atony results, a fact which favors the idea that this nerve plays some part. Brücke concludes with the notion of two different and distinct tonuses, namely, the tonus of rest and a tetaniform tonus, the latter, perhaps, being connected with different anatomical substrata (sarcolemma and fibrils).

Observations on Tissue Regeneration in Man.—A. Bier sums up the data contained in nine former articles published in the *Deutsche medizinische Wochenschrift*. Transplantation may give very successful results, although it has been much decried. Bone transplantation is the most successful of all, and although that of the epidermis succeeds it does not prevent cicatricial formation. Skin transplantation gives more favorable results. Nerve and muscle do not take kindly to transplantation, while blood vessels do fairly well. Connective tissue (aponeurosis, fat) generally gives rise to trouble when transplanted. These differences can be explained by two tendencies unequally present in the different tissues, namely, a regenerative tendency and a toxic, cicatrizing tendency. Bier discusses the tissue culture media and finds that the artificial ones have given poor surgical results. Blood as a medium is good for bone and connective tissue only, while for other tissues sero-lymphatic fluids are to be preferred. But the physiological lymph medium cannot be replaced by any kind of seric product, such, for example, as hydrocele fluid. The introduction of foreign bodies into wounds can only favor cicatrization and in no circumstances can it give rise to true tissue regeneration (Glück's method).

Wiener medizinische Wochenschrift.

February 23, 1918.

New Knowledge on the Cutaneous Lymphatic Reaction. The Pathogenesis of the Bullae of Pemphigus.—F. Samberger attributes a mechanical origin to pemphigus and not one of degeneration. The title is one that raises expectations and we will closely follow the writer, who tells us that a bulla is an accumulation of lymph in the papillae and epidermis. Its pathologic sig-

nification is quite the same as that of urticaria, excepting that the latter process localizes the lymphatic exudate in the chorion of the skin. Urticaria appears as a reaction resulting from vasoconstriction in tissues arid of oxygen. The writer next considers the signification of the bulla of pemphigus. He has met with bullae in a patient presenting a distinct clinical picture of vagotomy. By aid of some rather subtle theoretical considerations founded on modern physiology of the sympathetic and autonomous systems, he comes to look upon the bulla of pemphigus as an exudate destined to supply the oxygen desired by the tissues. This reaction is a response to the vasoconstriction and is identical to the reaction of urticaria excepting as regards its histologic localization. The localization in the papillae and epidermis likewise explains the long duration of the bullae as compared with the efflorescence of urticaria. In point of fact the bulla of pemphigus has not the many lymphatic tracts at its disposal which in the case of urticaria drain away the exudate. As to the vasoconstriction, the principal factor of the lesion, it is due in vagotonic pemphigus to a temporary irritation of the sympathetic from the substance destined to paralyze it. To the excitation of the vessels by the chorion the organism responds by a urticaria, while the pemphigous bulla represents the same reaction in the case of vasoconstriction of the vessels of the papillae.

The Open Treatment of Wounds of Warfare Combined with Solar Rays.—O. E. Schulz, by this literary offering, produces in print a typical example of German plagiarism, the subject matter merely containing the theoretical views of, and the practice employed by, the French surgeons for the past two or three years. Further comment is unnecessary.

Finska Läkarellskapets Handlingar.

November, 1917.

Therapy of Ulcer Peritonitis.—Wetterstrand, who wrote his graduation thesis on this subject in 1912, has continued his interest in the same and now reports a series of forty-seven cases of gastric and duodenal ulcer perforations operated on during 1909-1917 in the Surgical Clinic at Helsingfors. Remarkable to state, there were far more cases of stomach perforation in males (forty men and two women), which quite inverts the percentages of other countries. Of diagnostic value is diminished area of liver dullness, present in 80 per cent. of perforations. The patients as a rule reached the hospital in the earlier hours after rupture—over a half within six hours and 80 per cent. within twelve hours—a fact of great prognostic significance. Over three-fourths of all the victims were saved (76.6 per cent). This good result is attributable in part to the relatively recent employment of primary gastroenterostomy (eighteen cases) and exact closure of the abdominal cavity (eight cases). Convalescence was remarkably rapid. The technique should be as follows: Exact suture of the perforation with following omentoplasty. In cases seen within six or eight hours and where prolonged intervention is not contraindicated a radical gastroenterostomy should be performed, followed by enteroanastomosis. The peritoneal cavity should then be accurately and methodically flushed and accurately closed. In neglected cases gastroenterostomy cannot be undertaken as a rule. After flushing, drains must be used, although the epigastrium can be closed.

Prosthesis in Lower Jaw Resection.—Avellan's material is from both civil and military sources, he having made a tour through German military hospitals during the present war. Many forms of prosthesis of the jaw and teeth are now in use, of which the Sauer-Hahl procedure seems to be the simplest of execution, while at the same time permitting the best cleanliness and in general yielding the best functional results. In one case which was at first unsuccessful a reduction of 1 mm. in the height of the oblique surface gave a good result. It is this capacity for molding which aids in making the method superior; it can be adapted, for example, to the changes due to progressive cicatricial contraction. The patient can chew hard food, the tooth surfaces articulate well, the stump of the jaw bone gives no trouble, swallowing is easy, and phonation clear. A soldier lost all of his lower jaw save the right ramus and a small portion of the body. Many vain

attempts had been made at different clinics to replace the defect. As a result of scar deformity the mouth had become constricted and patient had a "bird face." In this case the Zimmer-Schroeder ball joint prosthesis was successfully used. The golden joint capsule was fastened to the two hindmost teeth of the upper jaw which had gold crowns. As a ball a bearing the size of a pea used for bicycles was used. The functional result was relatively good, but the chewing force was below normal and the voice was not distinct. Further treatment was refused. The method seems the best for such extensive loss of bone, as the Sauer-Hahl method is best in the less severe case.

Lo Sperimentale.

February 12, 1918.

Conservation and Utilizability of Vaccines.—Rondoni states that under the most favorable circumstances the antityphoid-paratyphoid vaccine loses much of its antigenic power in a few months, and should not be employed after the first four months. The agglutinability and precipitability in vitro may be conserved for eight months. Serum obtained from fresh vaccine protects the guinea pig from a dose many times fatal of the culture in doses up to 0.002. If a vaccine eight months old is used the corresponding figure is 0.05. Anticholeric vaccine aged four months has lost much antigenic power in rabbits, as much as the antityphoid-paratyphoid *B.* loses in five months or more. Hence it should only be used for the first three months.

Diabetes Insipidus from Hemorrhage in the Neurohypophysis and Its Peduncle.—Luzzatto concludes that in man the syndrome of insipid diabetes may be due to destructive lesions of the neurohypophysis and its peduncle, with the other formations in the infundibular region intact. These lesions may be accompanied by a state of grave cachexia similar to that seen in animals after total hypophysectomy or section of the peduncle. Spontaneous hemorrhages may occur in the hypophysis which correspond histologically to those seen in the nervous centers.

Experimental Researches in Phagocytosis.—Amato concludes that the phenomena through which substances with opsonic power are bound to the bodies of bacteria are regulated quantitatively by the same laws through which bacteriolytic sensibilization is bound with the bacterial protoplasm, the hemolytic sensibilization with the erythrocytes, and the agglutinins with the corresponding bacteria. In such reactions antibodies and antigens are not bound in constant quantitative proportions, but the quantity of antibody which is bound to a given quantity of antigen diminishes with the increase of the quantity of added antigen. The ratio between the quantity of bound antibody and that in the serum tested increases with the quantity of antigen added to a fixed quantity of serum.

Etiologic Studies of Certain Cases of Intestinal Infection of Diarrheal Type.—Zirone and Capone refer to certain epidemics of diarrhea in a military zone which present common characteristics, and may be grouped according to causation. In one group of cases the latter was apparently an infection with a protozoon. Here belong amebæ, which the authors have not personally studied, but which have been described in the laboratories of the zones in question. In the second group of cases various bacilli of dysentery were found, including the Shiga-Kruse and Flexner types. Finally, there is a third group which may ultimately be shown to be due to bacilli analogous to the paratyphus.

La Presse Médicale.

February 28, 1918.

Lumbarthria (Chronic Lumbar Rheumatism).—Leri does not refer to a lumbalzia or lumbago in the ordinary sense, but an affection of the lumbar vertebræ which formerly occurred in those above forty years of age. It has never been seen in a purely spinal localization, for various joints and members are also attacked. It goes from bad to worse, leading to muscle atrophy and bony ankylosis. In some cases the dorsal vertebræ are involved. Although before the war there were no reports of cases in the first half of life, the author has

seen examples in the third and fourth decades in soldiers in whom the symptoms showed wide departures from text book descriptions. The soldier is admitted for lumbago or sciatica, for like the latter it is chiefly unilateral (lumbago, however, should be bilateral). Upon examination the lumbar spines seem prominent, or, in other words, physiological cardosis seems effaced. If the patient lean forward this lumbar prominence is more marked and may be regular like the arc of a circle or uneven and wavy. In any lesion of the spine the muscles tend to immobilize the latter through contracture. The author, however, is able to exclude the latter element, the immobilization being due to ordinary active contraction in which muscular functional integrity is conserved. Passive mobility is strikingly well preserved. With the weight off the patient the spine seems to retain its suppleness, as shown in various tests, such as raising the patient by his thighs. At first sight this mobility seems to exclude the possibility of inflammation of the bones, but radiographs tell the story, as do also certain old museum specimens, for there is a production of osteophytes in association with osteoporosis. Seen in relatively young subjects apparently for the first time, one must see a new development and seek a cause nexus for it. It cannot be due wholly to active military life, for cases date back before mobilization. Syphilis can be excluded as an important factor. Nevertheless, as a whole it may be regarded as an affection revealed by radiography in soldiers. The elements in the cause nexus must be found in military conditions, as sleeping on the damp earth or straw, trench life, overwork, packing heavy loads. Dampness and fatigue are two factors which assert themselves in the spine. We should have a "pathology of the spine" in which all such factors receive due attention. Other spinal affections of the present war comprise campptocormy or bent trunk, which is functionally motivated and occurs especially after shell shock, etc.

Cancer and the War.—Sallmann cites Kirchner to the effect that cancer in Prussia during 1915 has shown a falling off, notably cancer in the digestive organs, which is to be attributed to the changed food conditions. The author made a local investigation for Breslau as based on hospital admissions and also found a falling off up to April, 1915; but since that period the disease has shown a notable increase especially in those under 50. These fluctuations cannot be brought into association with food problems. A favorable influence certainly cannot be imputed to dietetic restrictions.—*Nederlandsch Tijdschrift voor Geneeskunde.*

Functional Paralysis from Disuse.—Hartenberg, as a result of two years of experience in war neurology, has come to regard this type of paralysis as very common. Otherwise stated inaction is the most frequent causal factor in functional paralysis. In the various post-traumatic paralysees, certain mechanisms are imagined—psychogenic, reflex, myopathic, etc.; while mere inaction is not borne in mind. After injuries to extremities the joints become stiffened and movements are difficult and painful. It is usually the patient with courage who recovers the use of his limbs while the hypobolic subject notably fails. A neuropath obsessed with a conviction of his insufficiency or a merely contrary subject, will not make the necessary effort. There are, of course, other factors present than inactivity, for in paralysis from disuse organic changes develop in time and involve all the tissues—nervous, muscular, articular, osseous, vascular, nervous, and cutaneous. These changes may of course be associated with other phenomena such as vicious attitudes as a result of immobilization due to dissociation of activity of flexor and extensor muscles. There is also a dissociation of sensation and motility. A psychic component may exist of the nature of inhibition on the one hand and of ties, spasms and tremor on the other. In such cases a predisposition doubtless exists. It is evident that in these instances there is a critical moment at which combined treatment meets with a satisfactory response. If this period is passed the prognosis becomes unfavorable. After a certain number of months, recovery is rare, and we may understand that when the stage of cortical inhibition is reached recovery is unlikely.

Book Reviews.

MILITARY SURGERY. By DUNLAP PEARCE PENHALLOW, S.B., M.D. (Harv.); Major Medical Reserve Corps, United States Army; Chief Surgeon American Women's War Hospital, Paignton, England; formerly Director of Unit American Red Cross European Relief Expedition. With Introduction by Sir ALFRED KEOGH, K.C.B., Director General Army Medical Service. Original drawings by the author. Second edition. New York: Oxford University Press, 1918.

THE first edition of this work was published in August, 1916, after the war had been in progress two years, so that it says much for the excellence of the material contained therein and the manner in which Dr. Penhallow has set it forth that another edition should have been called for in less than two years' time. The first edition was up to date but owing to the rapidity with which views as to treatment of wounds change, it has been found necessary to revise thoroughly the chapter on treatment and bring it in accordance with the latest methods. The author considers that the Carrel-Dakin method is highly satisfactory, better by far, according to his experience and that of his coworkers, than the use of the saline solutions. A feature of the book is that its illustrations are from original drawings by Dr. Penhallow and are uniformly excellent.

THE PRACTICAL MEDICINE SERIES. VOL. VII. OBSTETRICS. Edited by JOSEPH B. DE LEE, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School, with the Collaboration of EUGENE CARY, B.S., M.D., Assistant Gynecologist, St. Luke's Hospital; Instructor in Gynecology, Northwestern University Medical School. Price, \$1.35. Chicago: Year Book Publishing Company, 1917.

THE remarkable feature about this annual is the degree of responsibility assumed by the editor who in this capacity is too often a mere figurehead. In this volume the abstracts, which appear to be chosen with great care, are carefully made, but in nearly every instance the editor exercises a sort of critical censorship which should possess great teaching values, and make the book of use to the undergraduate, for whom such works are not usually adapted. These comments illustrate fully the danger of accepting as progress many efforts which pose as such. However, when reinforced by wise commentaries, the general result is the desirable one of commingled progress and conservatism.

THYROID AND THYMUS. By ANDRÉ CROTTI, M.D., F.A.C.S., LL.D. Formerly Professor of Clinical Surgery and Associate Professor of Anatomy at Ohio State University College of Medicine; Member of the American Medical Association, Ohio State Medical Association, Columbus Academy of Medicine, American Association of Obstetricians and Gynecologists. Society for the Study of Internal Secretions, Honorary member of the West Virginia State Medical Society, Surgeon to Grant and Children's Hospital, Columbus, Ohio. With 96 illustrations and 33 plates in color. Price, \$10.00. Philadelphia and New York: Lea & Febiger, 1918.

THIS is really a complete book on the thyroid and thymus glands. The writer gained his experience partly in Switzerland, where certain forms of goiter are more prevalent than anywhere in the world, and partly in this country. When in Switzerland Dr. Crotti worked under such authorities as Kocher and Henry Stilling, so that he can claim to have had clinically a very wide experience, while theoretically he learned from the best masters. Upon this foundation he has added a great deal of material drawn from his personal experience, besides gathering all that he considered of value from the vast mass of French, Italian, German, and English literature on the subject.

With regard to iodine in its relation to Graves' disease, Crotti says that we have the right to infer that glandular hyperplasia in this disease is due to a "more or less marked lack of iodine," that the severity of the disease is in direct proportion to the diminution or absence of iodine in the gland, and consequently that iodine treatment is the only logical treatment of the condition. On the other hand, nothing has been better demonstrated than that iodine is not the specific treat-

ment of exophthalmic goiter. The reason for such inconsistency, according to Crotti, is very likely simply because glandular hyperplasia in Graves' disease and glandular hyperplasia found as a compensatory process after partial extirpation of the gland are due to two absolutely different conditions corresponding to two absolutely different processes. Similar does not mean identical, and because glandular hyperplasia in both conditions has a histological resemblance, nothing proves that their chemiopathological functions are the same.

Concerning the differential diagnosis of goiter the author is explicit, but points out that differential diagnosis between strumitis and malignant goiter, although, as a rule, without difficulty, is sometimes not easy. Crotti deprecates the administration of iodine during too long a period or in too large doses, but for simple goiter has devised a tablet composed of sodium arsenate, potassium iodide, sodium phosphate, thyroprotein, and salol. For exophthalmic goiter he uses tablets containing sodium arsenate, sodium phosphate, salol, sodium bromide, sodium bicarbonate, and calcium oxalate, and tablets containing pituitary gland, suprarenal gland, pancreas, corpora lutea. These tablets are prescribed simultaneously.

He also sketches a course of treatment for each given case. The various operations for the relief or cure of the condition are described in detail.

The work is profusely and artistically illustrated in colors and black and white, and in addition to being an exhaustive text-book from the practical and theoretical standpoints on all that concerns the thyroid and the thymus, is a beautiful specimen of the printer's craft.

MILITARY ORTHOPEDIC SURGERY. Medical War Manual, No. 4. Prepared by the Orthopedic Council. Price, \$1.50. Philadelphia and New York: Lea & Febiger, 1918.

FOR so small a manual (it measures 6 inches by 4½ inches) the number of illustrations as well as their quality is remarkable, nor could anyone believe that so thin a volume could contain over 250 pages. There is also room for a good index and a supplement with a number of blank pages for notes. The subject matter is novel throughout and there is no room for the subjects of re-education of the incapacitated, which is not called for in a pocket manual. The subjects on soldier's foot, military orthopedics (after gunshot injuries), ischemic paralysis, bonegrafts and nerve injuries all receive consideration in special chapters.

PHYSICAL DIAGNOSIS. By W. D. ROSE, M.D., Lecturer on Physical Diagnosis and Associate Professor of Medicine in the Medical Department of the University of Arkansas. Price, \$4.00. St. Louis: C. V. Mosby, 1917.

IT is a difficult task to add anything really new to the subject of physical diagnosis. The field is so well covered by a number of admirable books brought up to date by successive editions, that the writer who ventures into this special branch of medical literature must of necessity draw largely from known sources. Such is the case with the present work. This criticism, however, in no wise detracts from the value of the book, for the author has succeeded in making a judicious selection of facts, which have been systematically assembled in clear and direct style. The volume contains 473 pages with numerous illustrations on plates and in the text, the majority of which are taken from standard works. The scheme of utilizing pathological data to assist in explaining physical findings is to be commended, as it enables the reader to visualize what is actually taking place in the body. The book is divided into four parts, viz.: Part I, thorax; Part II, abdomen; Part III, head, neck, and extremities; Part IV, nervous system. Certain points in the examination of the mouth, nose, and throat are not sufficiently emphasized, as, for instance, the importance of searching for evidence of infection about the teeth, tonsils, etc., and employing the x-ray to detect such foci when they are not readily recognized by ordinary means of examination. Under the nervous system the Barany tests are given, and tables are appended showing the clinical facts upon which equilibrium tests are based. This is a worth-while feature. The book is primarily designed for medical students and the busy practitioner to whom it should particularly appeal.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 25, 1918.

THE PRESIDENT, DR. HOWARD C. TAYLOR, IN THE CHAIR.

Resolutions on Narcotic Drug Investigation.—The Committee on Narcotic Drug Investigation, consisting of Dr. Frank Van Fleet, Dr. Jacob Diner, and Dr. Gustav G. Fisch, made the following report: (1) After carefully considering the matter of drug addiction we have come to the conclusion that the addict is entitled to the same medical care vouchsafed any other diseased or afflicted person, and that therefore any addict, when arrested, should be referred to an institution for proper treatment. (2) We recommend that a certain number of beds or a definite Ward be set aside in every public hospital for the treatment of drug addicts. (3) We further recommend that the Narcotic act known as the Whitney bill be so amended as to prohibit ambulatory treatment of drug addicts. (4) We again recommend that all private institutions for the treatment of drug addicts be placed under State supervision, and (5) We recommend the repeal of Section 248 with reference to the compulsory record of an occasional administration of narcotics to a patient not an addict.

These recommendations were discussed and voted on seriatim. After discussion it was voted to omit the latter clause of No. 1, beginning "and that therefore any addict, etc." It was voted to omit No. 3 entirely. The other recommendations were adopted as read.

Resolutions Supporting the Owen Bill.—A set of resolutions describing the provisions of the Owen-Dyer bill, showing its importance to the medical profession, and asking the active support of the members of the Society, were adopted. A copy of these resolutions was sent to Congress, and the individual members of the Society were requested to write to their representatives urging them to support this bill.

Resolutions Asking Amendment to Traffic Regulations.—The following resolutions were adopted: "Whereas unintentional minor infractions of the law work hardship upon those physicians who from necessity or choice do not employ the services of chauffeurs. Therefore, *Resolved*, That the Medical Society of the County of New York favors an amendment to the city ordinance, or Traffic Regulations of the Police Department, excepting physicians from the operations of the rule now in force forbidding an automobile to stand unattended more than twenty minutes. *Resolved*, That a copy of these resolutions be forwarded to His Honor, the Mayor of the City of New York, to the President of the Board of Aldermen, and to the Police Commissioner, and that said resolutions be given wide publicity.

The Narcotic Drug Addict.—Dr. ERNEST S. BISHOP read this paper. (See page 752.)

The Problem of Narcotic Drug Addiction of To-day.—Dr. CHARLES F. STOKES presented this paper. (See page 755.)

Dr. JOHN H. BRUSH expressed the opinion that there was no occasion for becoming hysterical over the drug addict so long as we had with us the victims of alcohol. The liquor sot was many degrees lower in every way, mentally, morally, and physically, than the drug addict. It was a disgraceful reflection on the profession of medicine to recommend that the drug addict should be treated only in an institution. The medical profession had among its members those who were responsible for the creation of this habit, and for its own protection it should rid itself of this class of men. The first thing to be done toward solving the drug addiction problem was to purify the medical profession. Dr. Brandeth suggested that for the use of physicians morphine be put up in containers holding one ounce having a paster on the outside on which to write the number of grains taken out and the date on which they were taken; in this way it would be easy to keep track of the amount of the drug a physician was using.

Dr. DOWNER said that mention had been made of the fact that after the Civil War many drug addicts were turned loose on the community and that after this war there would also be thousands of drug addicts. Dr.

Downer said that in 1913 he was in Serbia and later in Russia so that his data were obtained at first hand. He personally had made thousands of drug addicts. The missiles of modern warfare were very different from those used in former wars and inflicted much more severe wounds. The modern bullet traveled with such increased velocity that when it struck a compact tissue as the bone of the femur, for instance, the destruction it occasioned was something terrific. When he went to Serbia he was stationed at a hospital where they had 1300 patients and only 300 beds. The patients they had were not ordinary patients such as one saw in a New York Hospital. These men came from the trenches with casts that had been on as long as six weeks and the casts were without windows for drainage. Such wounds were of course in extremely bad condition. These patients were put two in a bed and they continued to arrive at the rate of 300 per day. They had to be placed on the floor and no one thought of the danger of drug addiction, but only of relieving the suffering. It was necessary to go around each day and pick out those who had frozen to death. When a man was wounded in the trenches he was given one-half grain of morphine, at the first dressing station he was given another one-half grain, and then he was taken to the base hospital where he was operated upon and received more morphine. He remained in the hospital from one month to one and one-half years, and during the first two months of that time he was receiving morphine. The cases in which the bone was infected were very painful indeed. In some instances water had not been available and they had used morphine. Germany, in bombarding the city, cut off the water supply and there were 4000 wounded men in the hospital and the suffering was terrific so each man received a hypodermic of morphine. Most of these men starved to death, but at least two-thirds of those that escaped were drug addicts. It was a common sight to see men using morphine. They passed the hypodermic around there as the whiskey bottle was passed in this country. Our own boys were over there fighting and were no more immune than the others and when they returned to this country the question was were they to be regarded as criminals or as sick men.

Dr. CHARLES F. STOKES in closing the discussion said he wished to add that the Medical Department of the Army was keenly alive to the problem of narcotic addiction in its relation to the wounded. It must be realized that the wounded accumulate in appalling numbers after some engagements and they had to wait their turn for treatment. It was obvious that for humane reasons relief from pain was indicated and morphine administered. It would seem that the danger of acquiring addiction was small, as the patients and the narcotics were under the control of competent medical officers. He said further that the Surgeon Generals' Office was actively engaged in combating contamination of the military forces through addiction introduced as an evil by unscrupulous sellers.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held January 15, 1917.

DR. SAMUEL A. BROWN IN THE CHAIR.

THE program of the evening was contributed by the Third Medical Division of Bellevue Hospital.

A Case of Disturbance of Internal Secretions.—Dr. MILLS STURTEVANT reported this case, which he said was presented because it seemed to raise the question as to the pathology of the development of secondary male sex characteristics in the adult female. The patient, a Russian Jewess, married, was admitted to the Third Medical Division of Bellevue Hospital, in October, 1915. She was then 42 years of age, and had been in this country for twelve years. She had been a pushcart peddler. Her family history had no bearing on the case. Her personal history was also negative, except for measles when she was 15 years of age, and a mastoiditis which was operated on when she was 24 years of age. She was the mother of three children, two living and one that died of enteritis at

the age of 4½ months. There was no history of venereal disease, and the Wassermann was negative. Her menstrual history had been normal until about nine years ago, when the time between periods began to lengthen and the flow to become scanty. After seventeen months of this irregularity the flow ceased altogether for a period of seven months. At the end of this period she began to have a scanty serous menstruation again. Since that time menstruation had been regular at times and at other times irregular. Prior to nine years ago she had a luxuriant growth of fine black hair on her head, reaching nearly to her waist. Nine years ago, when she began to have the scanty menstruation and the amenorrhea, she noticed a growth of black hair making its appearance on her chin, upper lips, and cheeks, masculine in distribution and appearance. During this time the hair on her head began to fall out and was replaced by a sparse growth of much shorter hair. She had been a strong, active woman, carrying, when her business demanded it, weights of 50 or 60 pounds. Seven years before her admission to the hospital she began to lose weight and strength, developed an insatiable thirst and appetite, marked polyuria, itching about the genitals, was unable to attend to her work, and finally was confined to bed. Her weight dropped from 169 to 125 pounds. She estimated her urine at five quarts daily. She was told at a dispensary that her urine contained sugar, and that she had diabetes. During the next seven years she was under treatment in several hospitals, though never for any length of time, being apparently a difficult case to manage. When she entered Bellevue she had been untreated for the previous eight weeks. She weighed 110 pounds. Her skin was dry and inelastic, hair sparse and short, and her cheeks, chin, and upper lip, unshaven for a week, showed a black beard and mustache of masculine appearance. The forearms, arms, chest, back, and shoulders were covered with a heavy growth of black hair. The speaker stated that Dr. Ernest E. Glynn, writing on the "Adrenal Cortex, Its Rests and Tumors, Its Relations to Other Glands, and Especially to Sex" (*Quarterly Journal of Medicine*, January, 1912), cited six examples of adrenal hypernephroma in young women associated with changes in sex characteristics. The author analyzed Dr. Glynn's series of cases and stated that the examination of this patient showed nothing demonstrably wrong with the uterus or adnexa. The sella turcica was apparently normal on x-ray examination. The kidneys were not enlarged, and there was no evidence of tumor connected with the kidney shadow. The diabetes was a moderately severe one. This was a case of development of secondary male sex characteristics in a woman going on over a period of twelve years without other evidence of hypernephroma of the adrenal cortex. The case was offered for the evidence it carried that hypernephroma of the renal cortex was not the whole pathology of this unusual condition.

Dr. FENTON B. TURCK asked whether in this case any clinical tests had been made with the various internal glandular extracts, whether he had tried suprarenal and pituitary extracts in gradually increasing doses, and if he had what such tests had shown.

Dr. STURTEVANT replied that some tests were made. They had injected adrenalin and made blood pressure observations at various intervals; these observations were made when the patient was sugar free, but they never gave any definite lead.

Obscure Gastrointestinal Hemorrhage with Report of a Case.—Dr. LUTHER B. MACKENZIE presented this paper. He briefly reviewed the literature to show that many gastroenterologists, in writing of hematemesis, made the statement that the vomiting of any considerable amount of blood was sufficient warrant for the diagnosis of gastric or duodenal ulcer. This was rather an overstatement of the facts; hematemesis did not always presage an ulcer, or, for that matter, any discoverable organic defect. In the systematic consideration of hematemesis attention should be directed to the determination of the origin of the blood. Extragastric hemorrhage might arise in (a) pulmonary tuberculosis; (b) epistaxis, and (c) esophageal varices. It was occasionally difficult to tell whether one was dealing with hemoptysis or hematemesis. The author briefly enumerated the evident causes of gastric hemor-

rhage without going into detail. These were: (1) Local disease (a) gastric or duodenal ulcer; (b) cancer, (c) varicose veins or miliary aneurysm, (d) acute congestion, (e) following abdominal operations, wounds of the omentum, and also operations on the appendix. (2) Passive congestion due to portal obstruction. This was seen in (a) cirrhosis of the liver, (b) portal thrombosis, (c) pressure by tumor or portal vein, and (d) secondary to chronic disease of the heart and lungs. (3) Toxic cases, including the infectious fevers, acute yellow atrophy, and the purpura. (4) Cases with an obvious focus of infection, the appendix, and gall bladder most frequently being the sites. (5) Splenic anemia or Banti's disease—hematemesis here was, in the majority of cases, from an esophageal varix. Balfour of the Mayo clinic had recently tried to implicate the spleen as a causative factor in the obscure cases of hematemesis. His plea the writer found not entirely convincing. Finally there was an obscure bleeding described by W. Hale White and called by Sir Cooper Perry gastrostaxis. W. Hale White had collected 29 cases, of which 27 were in females. He called attention to the fact that this gastrorrhagia was very rarely seen after forty years of age. It was assumed that it was a vicarious hemorrhage and so described. Later, as the surgical treatment of gastric and duodenal ulcer developed, numbers of these cases came to operation, and instead of ulcer was found an oozing of blood from the gastric mucosa. Hale White did not think the condition was a vicarious menstruation, but suggested an analogy between the two conditions, oozing in both, the mechanism being illy understood. Many of these patients suffered from indigestion and epigastric pain in addition to hematemesis and melena. The amount of hemorrhage varied, and recovery was the usual outcome. The history of such a case might be very similar to that of ulcer, as the following case served to show. This patient was a young man, 21 years of age, admitted to the hospital on November 5, 1917. His family history was negative except that his father and brother died of tuberculosis, twenty and four years ago, respectively. His personal history was also negative. He had had measles and pneumonia, with a good recovery. On November 4 he was suddenly seized with nausea and vomiting, and noticed blood in the vomited material. The following day he was seized with dizziness and fainted. Later he vomited a large amount of dark brown material. He was then sent to the hospital. He gave a history of attacks of indigestion for a period of eight years. He described the pain as dull in character, being felt in the epigastric region in the median line. It sometimes awakened him at 1 A. M., and at other times occurred three to three and one-half hours after eating. Tightening the belt seemed to aggravate the pain, while drinking hot water relieved it. Small quantities of food had no perceptible effect. Careful clinical, laboratory, and x-ray examinations were made. The x-ray of the chest showed hypervascularization of the right lung, but the pulmonic markings did not fuse. A diagnosis of tuberculosis could not be made on the results of the x-ray examination. The x-ray examination of the stomach and duodenum seemed to warrant the diagnosis of duodenal ulcer. The patient refused operation. Ten days after his admission to the hospital his condition grew much worse, so that operation was not considered advisable. Death ensued in a few hours. From the autopsy examination an anatomical diagnosis was made of tuberculosis of the left apex with basal pleurisy and tuberculosis of the right kidney. There was fibrocaseous degeneration of the right adrenal and slight congestion of the spleen. The cause of death was not determined, possibly a virulent pneumonia in the left lower lobe in the stage of congestion. From a consideration of this case it must be admitted that no adequate cause for the bleeding could be ascribed, unless the case was placed with that group of cases described by W. Hale White as gastrostaxis, and even then no cause could be given, for the etiology of that condition was unknown. The writer felt that loath as we were to create new terms, with our present limited knowledge we could not do better than to retain the term gastrostaxis, and that the case herein reported was properly included. The case served to emphasize that cases of gastrostaxis might closely resemble duo-

denal ulcer and that the x-ray was not an infallible guide in diagnosis.

Dr. FENTON B. TURCK said he thought it might be of interest to bring out a few experimental points that might be of some service in clearing up somewhat many of these cases of obscure hemorrhage, that were really much more common than was generally recognized. It was well known that operations were often performed for ulcer in patients in whom the symptom of hemorrhage had been present, and no ulcer found. In his experimental work Dr. Turck said he had found that in feeding animals intestinal flora the bacteria migrated to the region about the pylorus, this being one of the selective sites. Of course, it was well known that we might have hemorrhages in other sites, as the retina, the kidney, or other parts of the body, but the hemorrhage occurred oftener in the stomach than in other parts of the body. The plates which he was exhibiting showed how after feeding large doses of intestinal flora the bacteria migrated to the region of the pylorus, and there was an anaphylactic action, sensitizing the walls of the blood vessels, with a resultant dilatation, venous stasis, and atony that permitted the bacteria to pass through the walls of the vessels, and as the dilatation increased the blood cells could be seen passing out through the vessel walls, and eventually there was a definite hemorrhage. Furthermore, the plates showed that such hemorrhage occurred from the veins and not from the arteries. These hemorrhages could be observed in other conditions as well, and had been shown to occur in shock. Dr. Turck cited instances in which an enlarged colon, with a resultant stasis and autointoxication had produced hemorrhagic symptoms suggestive of duodenal or gastric ulcer. It was well known that foreign proteins, being in colloidal suspension, would, according to the laws of the diffusion of colloids, pass through the lumen of the intestine. Autointoxication, anaphylaxis, venous stasis, etc., produced changes in the vessel walls that led up to hemorrhage. It was quite possible to have such hemorrhage, without a rise in temperature and without alarming symptoms, that might result fatally in a comparatively brief period of time.

Dr. GEORGE B. WALLACE said that Dr. Turck had shown experimentally the same thing that was found in septicemia; one might have similar hemorrhages in septicemia, although there would be also a general infection which Dr. Turck had been able to avoid.

In Dr. MacKenzie's cases there appeared to be a complete absence of local changes in the gastric mucosa, while Dr. Turck's experiments seemed to show definite structural changes, at least in the blood vessels. He would like to ask if a microscopical examination was made of the gastric mucosa in Dr. MacKenzie's case. It was very puzzling to understand how there could be a hemorrhage such as Dr. MacKenzie described without any visible change in the stomach or intestinal mucosa. The word gastrostaxis did not explain anything of the pathology of the condition.

Dr. MACKENZIE, in closing the discussion, replied that the gastric mucosa had been examined microscopically and the pathologist was unable to find anything abnormal. The treatment for a duodenal ulcer that bled was excision, or cauterization of the ulcer with a gastroenterostomy, gastroenterostomy alone not curing the bleeding. As to the possibility of this case being due to erosions which had healed, it was examined just one week after the hemorrhage had occurred, and if erosions had been the cause there would still have been some evidence of them. Mayo Robson reported that at operation he had watched the bleeding or oozing from the gastric mucosa. These cases of gastrostaxis gave a history of gastric pain or distress for quite a long time, as did this case. As this case had no organic basis for the bleeding that could be discovered, and symptomatically was like those cases in which oozing had been observed, it had therefore been assumed that it was, too, a case of oozing or gastrostaxis. Dr. W. Hale White considered gastrostaxis analogous to menstruation, oozing occurring in both, but admitted that he was ignorant of the etiology. The term gastrostaxis should, therefore, be reserved for oozing of blood from the gastric mucosa of obscure origin.

Treatment of Twenty Cases of Group I Lobar Pneumonia with Serum.—Dr. JOSEPH E. CONNERY made this presentation, which consisted of a tabulated analysis of this series of cases. The conclusion to be drawn from his observations was that all cases of pneumonia should be given the serum treatment, regardless of the type of pneumococcus present.

Dr. T. STUART HART congratulated the reader of the paper on his interesting presentation of his cases of lobar pneumonia. He said, however, that he would hesitate, in the present state of our knowledge, to use serum in all cases of lobar pneumonia. It seemed to him best, as yet, to confine treatment to the cases of lobar pneumonia which belonged to the specific type for which serum had been prepared. Practically all patients who were treated with serum suffered from serum sickness. Serum sickness made the patient very ill for a few days, although Dr. Hart had never seen a fatality following the administration of serum. Any one who had watched the patient go through a serum illness would not want to subject a patient to this unless he was definitely assured of some benefit to the patient. It seemed to him that one ought, therefore, use serum only in cases of Group I. He thought that we should regard the use of serum as still in the experimental stages. In his opinion the most important proof of the value of serum was in its power of sterilizing the blood stream. In Dr. Connery's report one case only showed a positive blood culture. These, of course, were the patients most seriously ill. These were the patients in which the use of serum was without question indicated. Until recently, Dr. Hart said, he had never had a patient, belonging to Group I, with a positive blood culture, in whom the blood was not sterilized forty-eight hours after the administration of the serum, if the patient lived that length of time. This record, however, had been recently broken. A patient in the Presbyterian Hospital with lobar pneumonia, Group I, had a positive blood culture. This patient had received five or six treatments of 90 c.c. each of the Rockefeller Hospital serum. In spite of this the blood stream never had become free from the organisms. In a consultation over this case, on account of this unusual finding, it was thought that the patient must have some focus of infection other than the lung, which was supplying pneumococci to the blood stream. The patient died a day or two later. At autopsy there were found vegetations on the valves of the heart which showed the presence of Group I organisms. This was undoubtedly the source of the prolonged presence of organisms in the blood stream. He felt most positively that a positive blood culture was a strong argument for the use of specific serum.

Dr. SELIAN NEUHOF disagreed with the last speaker, and emphasized Dr. Connery's point that the serum should be used on every case of lobar pneumonia. He recalled a series of cases of pneumonia from the Lebanon Hospital that he had reported in the *New York Medical Journal*, June 2, 1917, in which he made the important point that if the serum was going to do any good it should be given early in the course of the disease, even before they knew with what type of organism they were dealing. When the clinical diagnosis of pneumonia was made the serum should be used, just as in diphtheria they gave the antidiphtheritic serum as soon as they had diagnosed the case as one of diphtheria, without waiting for the report on the culture. This was especially of importance in private practice where one did not have the facilities for a rapid laboratory diagnosis. Dr. Harlow Brooks, at Camp Upton, was following the procedure above outlined, namely, giving the serum at once, and then isolating the type of bacterium afterward. At the time the speaker read his paper one of Dr. Cole's assistants brought up the point made by Dr. Hart, but the speaker believed that a delay of twelve to twenty-four hours made such a difference in results that one should have the serum on hand and use it at once when the case had been diagnosed as one of lobar pneumonia.

Dr. MACKENZIE called attention to the fact that there was a school at the present time which thought that pneumonia was a bacteremia. Dr. J. C. Wilson of Philadelphia had found the organism in the blood in 75 per cent. of his cases. Dr. Cole and others thought the septicemia occurred only in the severe cases.

A Case of Polyserositis.—Dr. LOUIS L. SHAPIRO presented this patient. He stated that the patient was a Russian who had come to this country fourteen years ago. He was a shirt operator, married, and had four children, all living and well. His family history was negative, his habits good. He used alcohol in the form of whiskey, one or two glasses daily, and an occasional glass of beer. He had had typhoid fever and made a good recovery. He had a cough lasting three weeks, fever, night sweats, and a loss of weight four years ago. Otherwise his history was negative. His present illness dated back three years, when he had cramp-like pain localized over the upper quadrant and central portion of the abdomen, followed about a week later by tremendous swelling of the abdomen and a sense of oppression over the upper portion. On the advice of his physician he entered St. Luke's Hospital on June 6, 1915, where he remained until June 19, 1915. The diagnosis made at that time was hepatic cirrhosis with thrombosis of a tributary of the portal vein. The patient then returned home, resumed his occupation, and enjoyed perfect health until two months ago, when a similar attack occurred. There was pain in the abdomen, marked abdominal swelling, more gradual in onset than on the previous occasion, and swelling of both feet and legs. He was admitted to Mount Sinai Hospital on April 9, 1917, and remained until May 24, 1917, being discharged as improved. Here again the diagnosis of hepatic cirrhosis was made. During his stay in the hospital paracentesis was performed twice, with the removal of 2500 and 5000 c.c., respectively, of serous, straw-colored fluid. The abdominal swelling entirely subsided and the patient again resumed his routine life, being apparently perfectly well. From September, 1917, until the present date he had had nine similar attacks, including the present one, and had been tapped three times at home, three times at Mount Sinai, once at Bellevue Dispensary, from which he was referred to Bellevue Hospital, and once since admission. He was tapped in all ten times in as many months. A careful physical examination made at the time of his admission to Bellevue Hospital led to the diagnosis of chronic adhesive pericarditis, serofibrinous pleurisy, thickened pleura, and ascites. On December 24 a paracentesis was performed, and 10,400 c.c. of fluid removed. Following this the liver was not palpable, and could not be made out enlarged. The spleen was palpable an inch below the free costal margin. It was firm, smooth and not tender. The temperature varied from 97° to 102°; it was 98.4° at the present time. The pulse varied from 64 to 104, and respirations averaged 22 a minute. The blood Wassermann was negative. The results of blood examination and blood chemistry were reported in detail, showing nothing very striking. The urine was negative. The feces were negative for ova. The ascitic fluid was straw-colored, specific gravity 1014. It showed no spontaneous coagulation. It contained 120 cells per c.c., mostly lymphocytes. The pleuritic fluid was serofibrinous, and showed 80 cells per c.c., mostly lymphocytes. The culture was sterile, being negative for tubercle bacilli. The writer stated that they considered both these fluids as low grade exudates, showing evidence of chronic peritonitis and pleuritis. The tuberculin test was negative. The x-ray examination of the gastrointestinal tract showed no evidence of new growth. The fluoroscopic examination showed distortion and irregularity of the cardiac outline, pleuro-pericardial adhesions, and left pleural effusion. The diagnosis of polyserositis was made because of the multiple involvement of the serous membranes, namely, the pericardium, pleura, and peritoneum, with the presence of the following symptom complex, first described by Pick in 1896, a sense of fullness and oppression in the upper part of the abdomen, preceded by the sudden onset of acute pain, occurring in cases of chronic adhesive pericarditis with ascites requiring frequent tapping; the absence of edema of the legs, which may be slight at the late stage, and absence of jaundice. The diagnosis of chronic adhesive pericarditis was made on the following: systolic retraction of changes in cardiac dullness on respiratory phases, imperfect descent of the apex beat during inspiration, occurring over a considerable area, the limited shifting of the apex beat on change of posture, the absence

absence of pericardial effusion in the presence of peritoneal and pleuritic effusions, and on the x-ray and fluoroscopic examination. The diagnosis of pleuritis was made on the physical signs, the withdrawal of fluid, with the character of a low-grade exudate, and the x-ray. The diagnosis of peritonitis was made on the frequent occurrence of the ascites and the character of the fluid. Hepatic cirrhosis (uncomplicated) might be ruled out on the following grounds: presence of ascites over a considerable period of time, requiring frequent tapping, with intervals of complete subsidence and perfect health. Hale White, in his review of cirrhosis hepatica, stated that patients did not survive long following paracentesis; they usually died before a second paracentesis was performed; absence of the etiological factors of cirrhosis; absence of gastrointestinal disturbance; absence of marked dilatation of the superficial veins of the abdomen; absence of edema of the lower extremities and jaundice, and the character of the ascitic fluid. Thrombosis of the portal vein extending over a period of three years would manifest some evidence of collateral circulation either superficial or deep. Tuberculosis of the peritoneum might be ruled out on the following grounds: absence of tuberculous history and habits; absence of tuberculous elsewhere, including negative eyegrounds for tubercles; absence of tubercle bacilli in ascitic fluid and pleuritic fluid; negative tuberculin test. Syphilis and so-called Banti's disease, which recently had been called a syphilitic manifestation, might be ruled out on the following grounds: absence of luetic history; absence of general lymph gland enlargement; absence of marked emaciation and anemia; (this is usual in the terminal stages), and absence of gastrointestinal disturbance. Malignancy, including abdominal new growth, was ruled out by the following: absence of marked emaciation; history of frequent tapings; lack of evidence of metastases elsewhere; negative x-ray.

Dr. W. J. PULLEY said he wished to dissent. This case was one that had been with one of his coworkers at the University Clinic. It was peculiar in that the patient was almost absolutely intolerant to fluid. If he took water it seemed to go immediately into the peritoneal cavity. That made him think that the trouble was due to a disturbance of the portal circulation. He had seen one similar case on the third medical division which proved to be due to a disturbance of the portal circulation. It was in a woman who came in shortly after pregnancy, and it was thought that she had a portal thrombosis. He believed this case of Dr. Shapiro would eventually be shown to be due to a disturbance of the portal circulation. The case, however, had been very well worked up.

Associated Incidents of Cardiovascular Leses and Syphilis of the Central Nervous System.—Dr. E. DAVID FRIEDMAN presented this communication. He stated that it had long been suspected that syphilis played an important part in the causation of aortic aneurysm, and reviewed the literature demonstrating this. He also reviewed the literature emphasizing the luetic origin of tabes, the occurrence of angina attacks, and other vasomotor and cardiac disturbances in connection with tabes, and stated that these cardiac complications usually came on late in tabes. It was observed by Ruge and Hurtner that in tabetics who developed cardiac disease the aortic valve was chiefly affected. Roge and Mueller, in 1906 and 1907, emphasized the fact that the frequency of this association of tabes and cardiac involvement were not sufficiently appreciated. Usually one of the two conditions dominated the clinical picture, and the symptoms and signs of the latent condition had to be carefully studied and elicited. The tabes in a case of aortitis might be very mild; likewise the vascular lesion in tabes may sometimes be found only after careful chest and x-ray examination. In Roge's and Mueller's twenty-four selected cases showing this association the most frequent lesion was aortic regurgitation, or aortic regurgitation and obstruction. In fifteen of the twenty-four cases there was tabes and aneurysm. Most of these fifteen cases showed myocardial degeneration and premature arteriosclerosis. In over 58.3 per cent. there were definite cardiac complaints. The cases of sudden death in tabes were probably due to dilatation from myocardial degeneration, coronary thrombosis, or rup-

ture of an aneurysm. In nine of these cases there was definite evidence of lues; in ten others it was probable. In only two of these cases was there a history of polyarthritis. Rheumatism in these cases usually meant tabetic pain. Of the twenty-four cases seven were women, and their average age was 40 years. Bittovt found the average age of nonluetetic aortic sclerosis to be 55 years. The cardiovascular symptoms came on later than the nervous symptoms. A focal lesion in the cord gave symptoms earlier than one in the aorta. In a case of cardiovascular lues the symptoms of tabes were usually very mild. The pupils might be miotic, rigid, or unequal, or irregular, the Achilles jerk might be lost, which was evidence of sacral tabes, which was an important group. There was hypotonus present even in cases with exaggerated knee jerks. The loss of tone, however, need not always be attended with loss of deep reflexes. There might be lancinating pains or gastric crises. There frequently was undue retention of urine, some of the patients taking pride in their ability to go all day without voiding. There might be tabetic flat foot, ulnaris hypoesthesia, or hypoesthesia of the anus or urethra. The absence of a history of rheumatism or other infectious diseases in a case of aortic regurgitation, the localization of a murmur in the second right intercostal space, or the occurrence of aneurysm in the young, was suggestive of cardiovascular lues, and the signs should be looked for with care. In radiographic examination aneurysmal bulging might be seen in the first oblique diameter, encroaching on the so-called retrocardiac space. Every case of tabes should be examined radiographically, and electrocardiographically, if possible, to determine changes in the cardiac musculature, to which Brooks first called attention.

Cases with myocardial changes occurring early in life, with dyspnea, anginal attacks, palpitation, cough and slight edema, should be examined for signs of tabes. Light would thus be thrown on many obscure lesions. For instance, a fixed pupil might clear up the luetic origin of an obscure liver affection, and the loss of the Achilles jerk might mask a stomach syndrome as a gastric crisis. In our times we were fortunate in being able to corroborate our diagnoses by means of the tests applied to the blood and spinal fluid, but we must respectfully express our appreciation of the best of clinicians who were able to perceive truth and make accurate clinical observations even without our modern laboratory aids.

Dr. Friedman said his own observations were made on 50 tabetic patients at the Central Neurological Hospital, among which there were eight cases of cardiovascular disease. Four of these were males and four females. These cases he reviewed. Two cases were recently seen in the Third Medical Division at Bellevue Hospital (service of Dr. Brown); one showed tabes, aortitis, and dilatation of the arch of the aorta, and the other aortitis, with a to-and-from murmur, and a basilar meningitis luetica involving the fifth, seventh and eighth nerves on the left side. Of three cases from the writer's private practice, one showed tabes and aneurysm, a second tabes and premature arteriosclerosis, and the third aortic regurgitation with dilatation of the arch, tabes, and general paresis. Through the courtesy of Dr. Douglas Symmers, he had had access to the records of the State Hospital for the Insane at Morristown, N. J., for the period 1907 to 1915. There were eighty-three cases of general paresis among them. Of these, the writer selected only those about forty-five years of age or less with changes in the aorta indicative of lues. There were forty-nine such cases, and among the remaining older cases the lesion in the aorta was a distinctive meso-aortitis luetica in thirteen cases, making a total of sixty-two cases with syphilitic aortic disease, or 75 per cent. In concluding, Dr. Friedman referred to the intraspinal treatment of tabes, stating that the cerebrospinal fluid was poor in antibodies, as was shown by the necessity of taking larger quantities of it than we did of the blood serum for the Wassermann test. In this way Hauptmann succeeded in obtaining many more positive fluids than had been obtained previously. We knew also the value of intrathecal administration of serum in cerebrospinal meningitis, where, too, the antibodies were introduced from without. The attempts to treat general paresis

with nucleic acid tuberculin really resolved themselves into efforts to stimulate the antibody mechanism, which we knew now was intimately associated with the incidence fever. So it seemed to the author that it was not so much a question of introducing salvarsan into the cerebrospinal fluid as of introducing antibodies. The value of a preliminary intravenous injection of salvarsan would consist in the destruction of spirochetes, with the consequent calling into play of the antibody activity of the blood. The injection of the patient's own serum would then furnish the antibodies which seemed to get into the cerebrospinal fluid with difficulty. It would be up to the immunologists to devise a means of concentrating the antibodies in the blood, and using them for therapeutic purposes.

Two Cases of Local Edema, One Showing Marie's Sign Group.—Dr. W. J. PULLEY presented this report, which he prefaced by stating that the title of the paper was misleading. What he wished to direct attention to was localized edema of the arm, forearm and hand in two separate cases and to bring them together for comparison. In the one case there was no change in the bones or soft parts of the hands and arms except for the edema, while in the other there was a demonstrable degree of morphological change both in the soft parts and the bones. In the first case a study of the radiograph made it seem probable that the pressure was from without on the return circulation, while in the other the cause of the edema was problematical. Both cases suffered with cardiac and blood vessel disease. In the first, the pressure case, the cardiac lesion was pronounced at the aortic orifice and in the aorta, while in the second case the heart lesion was more definitely located at the mitral orifice, showing both an obstructive and a regurgitant murmur. The bone changes were found in the case in which the pulmonary circulation was interfered with. This case presented the unusual condition known as Marie's sign group. By this was meant that the fingers were clubbed and there was a rarefaction of the radius and ulna at the lower ends, and an apparent condensation of the shafts of the metacarpal bones and phalanges bones was a very gradual process, much slower than only on the affected side. The rarefaction of the long the clubbing of the fingers, and it might be that the first step toward rarefaction was the apparent compactness of the bone on this side as compared with the other, and the narrowing of the bone canal might be followed later by rarefaction. Dr. Pulley said that it might be recalled that, in 1890, Bierre described the Marie sign complex and called it pulmonary hypertrophic osteoarthropathy. In his description of some of the cases not only the long bones and their joints were involved but also in some cases the bones of the face were affected. Further investigation showed that those cases in which the bones of the face were affected were cases of acromegaly. Clubbing of the fingers and curving of the nails invariably occurred in Marie's sign group. In a gradual manner morphological changes then followed in the ends of the long bones and their joints. In the great majority of cases the condition was bilateral. More recently observations had shown that the name pulmonary hypertrophic osteoarthropathy was misleading, indicating that a lung poison was necessary for the production of this condition, in that the disease had been observed in connection with other diseases in which the lungs were normal. It had been observed in fibrous pyloric obstruction, in cancer of the esophagus, in cirrhosis of the liver, and in other chronic conditions. It was just possible, however, that any one of the diseases just mentioned might produce an obstruction to the pulmonary circulation by impeding the action of the diaphragm and very quickly producing dilatation of the right ventricles. Two principal theories had been advanced as a cause of this condition—first, the mechanotoxic, and, second, the neurotrophic. The first maintained that there must be a lung toxin present in addition to the mechanical obstruction to the blood current. The second and later, the neuropathic theory, maintained that lesions below the pons very often produced trophic changes in the bones and soft parts of the affected side or part. These cases were still under observation, blood examinations were being made, and a more complete report would be possible later.

THE TREATMENT OF TUBERCULOSIS.

BY COL. G. E. BUSHNELL.

M. C., U. S. ARMY, RETIRED.

WASHINGTON, D. C.

IF an animal of experiment, a guinea pig or rabbit, is inoculated with a large dose of virulent tubercle bacilli the result is inevitably death within a few weeks or months. It matters not what treatment is employed; no amount of rest or fresh air is of any avail, and liberal feeding can only slightly prolong life.

Why, then, it may be asked, is there reason to hope for benefit from such inadequate helps as fresh air, rest, and food in the tuberculosis of man? The answer is, that the animal has never been in contact with tuberculosis and has had no opportunity to acquire the heightened resistance as the result of such contact which we call immunity. The young child or the uncivilized adult who receives large or, what amounts to the same thing, frequently repeated doses of tuberculous poison without having had any previous experience with tubercle bacilli dies as certainly and speedily of tuberculosis as the animal of experiment. Animals, including man, differ as to their susceptibility to different strains of the tubercle bacillus and to the tubercle bacillus in general, but given a sufficient primary dose of tubercle bacilli virulent for the species, the result is always the same—death in a few weeks or months, provided that this dose is really the first one received. Moreover, the form of the disease is an acute generalized tuberculosis which bears little resemblance to the pulmonary tuberculosis with which we are familiar.

But animal experimentation has abundantly shown that if an animal is given a small amount of tubercle bacilli as an initial dose, and if sufficient time elapses between doses, when a second and much larger dose is given, the result obtained is very different. The animal either experiences no ill effects whatever from the second dose or is very slightly affected by it in comparison with the deadly effect from the large primary dose, the results varying somewhat with the species and to some extent with the individual. There can be no question that these facts are applicable to the tuberculosis of man, that the reason why our patients do not die, as a rule, of acute tuberculosis, but have a chronic and limited form of the disease is because they have had small immunizing doses of tubercle bacilli and have acquired a

certain immunity. A non-resistant animal which receives an intravenous injection of pneumococci does not die of pneumonia, but of pneumococcus septicemia. A certain amount of resistance is demanded in order to localize the disease as a pneumonia. Just so the non-resistant animal dies of generalized tuberculosis after a large dose of tuberculosis and only the relatively immune animal acquires tuberculosis limited to the lungs. But pulmonary tuberculosis as it usually presents itself manifests a tendency to cure or at least a tendency to become localized; so many years of conflict are required in many cases before it succeeds in having its own way with the patient that there can be no doubt that an immunity is present and that it is an immunity of a very high degree.

Supposing now that the patient has this high degree of immunity, that there has been only a slight lapse from the state of absolute immunity, it is reasonable to believe that comparatively slight remedial agents, a little improvement in the conditions of life, a little rest, somewhat better and more abundant food and the like, may suffice to assist the patient's organism to make the comparatively slight effort demanded to acquire again the state of absolute resistance to the tubercle bacillus. What we seek by our treatment is not to find agents that shall destroy or inhibit the tubercle bacillus, as much as to help our patients to restore their own immunity. Countless drugs have been useless, or worse than useless, in combatting tuberculosis because they have been employed with a false idea. They have been selected with a view to destroy the tubercle bacillus, or to cure some symptom such as cough, not with a view to strengthening the resistance of the patient, or restoring his immunity. It may be doubted whether any drug will ever be found that will have any material effect in impairing the activities of the tubercle bacillus, but it is quite easy to name numerous drugs which will have an injurious effect upon the patient. In the present state of our knowledge it may be laid down as an axiom that anything that is bad for the general health of the patient is bad in the long run for his tuberculosis. On the other hand, the making of antibodies against the tubercle bacillus is a function of the nutritive activities of the cells of the body. Hence anything that favors a more perfect nutrition is of benefit in helping to regain the lost immunity. The agents that have been found to be helpful in this regard are better oxygenation from abundance of pure air, rest to restore the weakened nerves of the patient and lower demands upon his reparative powers, and good food well assimilated. These constitute the tripod

of treatment; with them wisely used wonders can sometimes be accomplished, but only, it should always be borne in mind, in cases in which there already exists an immunity which is capable of reinforcement. Some patients get well, in spite of gross neglect of treatment; others are cured only by much careful treatment; still others die with tuberculosis which advances inexorably from the very outset, no matter what treatment we may adopt, the result in the individual case depending fundamentally upon the degree of immunity which the organism is capable of attaining.

In tuberculosis we prescribe not medicine, but a mode of life. It is a simple matter to write prescriptions; it is difficult to work upon the patient's mind so effectively that he will be willing to change entirely his mode of living and to persevere in the new way for months, perhaps for years, often through his whole life. To do this requires much patience and zeal. The physician must have faith in the treatment that he prescribes; he must really believe what he says when he strives to influence the patient. You can deceive a patient for a little while, but he will detect shams in daily intercourse which extends over months. The physician then must have the zeal of a missionary seeking converts. He must also have a knowledge of the reasons why certain things are necessary in treatment and be able to present these reasons so convincingly as to persuade the patient to receive them and be guided by them. And, thirdly, the physician must have skill in diagnosis to determine the exact condition of the patient so that therapeutic measures, like exercise, rest and feeding, may be so prescribed as accurately to meet the patient's varying needs.

The psychical side of treatment is that which is most neglected, yet in it the most notable successes are attained. Some physicians expect their patients to be morally weak, to demand amusement, to need diversion, to be unable to exist without the presence of their families, and they excuse harmful exercise on the ground that otherwise the patient will become despondent. No good results are ever attained in that way. Others consider it necessary to keep up the patient's faith in treatment by the use of drugs, which are given as placebos, not because they are of therapeutic value. And they will tell you that as the course of the disease is long it will be necessary to frequently change the drugs employed, in order that the patient's hopes may be kept alive. This also is a device of the faint-hearted and the pessimistic. They are trying to deceive their patients and must inevitably fail in the long run. The patients may not indeed believe that they are being deceived, but they will infallibly lose faith in the efficacy of the medication.

The physician with faith and zeal will endeavor to bring the patient's will to assume command. He will encourage optimism and perseverance, a resolute putting away of doubts and fears, a stout-hearted determination to endure cheerfully a monotonous existence. The patient, to be a successful patient, must himself have a good deal of the philosopher in his make-up. The writer's experience leads him to believe that fully

two-thirds of the patients can be successfully influenced psychically. Intelligence in the patient is much to be desired, but not all intelligent patients can be influenced. Next to a good immunity and a good physician the third most important desideratum in the treatment is faith in the physician and willingness to co-operate on the part of the patient.

Rest.—The influence of rest in abating the severity of an inflammatory process is well known. Especially important in tuberculosis is rest with a view to lessen the volume of the pulmonary lymph. The effect of motion and of friction in spreading infection from a suppurating focus is a familiar surgical fact. As Tendeloo has pointed out, it is probable that extensions of tuberculosis in the lungs are caused in a similar way. The diseased portion of the lung, having lost some of its elasticity, expands less than the neighboring healthy portions and at the same time contains a greater amount of fluid; hence the possibility of the suction of lymph, presumably contaminated with tubercle bacilli and their poisons, from the focus into the healthy lung through the numerous anastomosing lymph channels. The danger of such extensions will naturally be the greater the more acute the inflammation, and consequently the larger the volume of lymph, and the more vigorous the respiratory movements. In other words, with relative rest of the parts the neighboring healthy lung will not be as likely to aspirate lymph from the tuberculous focus, partly because from the favorable influence of rest there will be less lymph to aspirate, partly because the suction will be less. From the foregoing it is evident that breathing exercises are contraindicated in the active stage of the tuberculous process. Not only should deep breathing be avoided, but motion of the upper extremities should be reduced to a minimum.

Rest is also highly desirable to promote cicatrization and encapsulation. Surgeons have discovered that the formation of fibrous tissue in wounds is greater when the parts are at rest than when they are in motion. So far as the lungs are concerned, the process may be explained as follows: Tendeloo has shown that a chemical irritant injected into the normal lung excites zones of inflammation the nature of which varies with the concentration of the irritant, there being a central necrosis, then fibrinous, then serous inflammation, last of all a zone of proliferation of fibrous tissue. Similarly, in tuberculosis the formation of fibrous tissue is caused by irritation from the poisons of the disease. Now there must be an optimum amount of irritation which will excite the growth of fibrous tissue to the greatest possible extent. The parts being at rest and the irritant being supposed to be produced as a constant quantity, the influence of the irritant will be most apparent at the distance at which the optimum stimulus is excited by it; connective tissue may perhaps be formed within and beyond that zone, but the efficient encapsulation will take place at the optimum distance. If the parts are in motion the irritant instead of exerting its stimulant effect over a certain limited zone will be diffused, now one and now another part of the tissues being

flooded by it, but there being nowhere a zone in which the optimal stimulation is steadily applied. The result of this will be a wider diffusion of less well-developed fibrous tissue, so that, while there may be in the aggregate a larger fibrous transformation its effectiveness as a capsule will be impaired directly as the extent of its diffusion.

And lastly, rest of the body is needed for its recuperation. In fighting its mortal enemy the body has two tasks, first to make antibodies against the tubercle bacillus; second, to erect fortifications in the shape of encapsulations. Both tasks have to be performed by an organism below par. Perfect nutrition is required for the complete success of the undertakings, especially for the more difficult problem of furnishing efficient antibodies, but the nutritive activities have to be exerted by cells more or less poisoned, more or less badly nourished, fed by blood that may be fevered, but which, whether fevered or not, is certainly tainted. Evidently with such tasks before it the organism cannot afford to waste its strength and substance in making unnecessary repairs, not only in replacing the cells of voluntary muscles, but much more in making up deficiencies of that mysterious force which we call nervous energy. If anything is certain in the therapeutics of tuberculosis it is that the most fatal injury that can befall the consumptive is the exhaustion of his nervous energy by over-exertion. We must then guard his scanty store of this most precious possession by every means in our power in order that what remains of it may be used only for the most necessary expenditures.

Rest, as we use the term in the treatment of tuberculosis, means, of course, necessarily only relative rest. There is no doubt—in the mind of the writer at least—that the nearer the patient can approach to a state of absolute rest, if he is more than slightly affected and if the disease is active, the better his chances of cure. An example will serve to show how great an improvement may be made by apparently slight differences in regimen. A physician with advanced and extensive pulmonary lesions and with a maximum temperature oscillating about 102° and 103°, was accustomed to dress every day, go down stairs, and spend the greater part of the daylight hours sitting quietly out-of-doors. When the writer assumed charge of the case he at once directed that the patient go to bed. To this the patient strenuously objected, saying that he would get weak in bed, would lose appetite, that he was not taking any exercise, etc. However, he finally went to bed with reasonably good grace. Very soon improvement in his condition became manifest, his temperature gradually dropped to normal and remained there, and the evidences of activity in his lesion abated and finally disappeared. The patient admitted, after six months in bed, that not only had he not become weak, but that his muscles were larger and stronger than they were when he took to his bed. Upon passing from under treatment the patient returned to the East. Here experts examined his lungs and told him that the disease was arrested. He became over-sanguine, exerted himself too much, and finally died. The case is cited as an evidence not only of the value

of nearly absolute rest as a curative agent, but also of the need of long perseverance with the treatment in advanced cases if durable results are to be obtained.

Sitting is an artificial posture which requires the constant contraction of certain groups of muscles. It is therefore not only a form of exercise, but a bad form of exercise. It is much better, therefore, for the patient to lie flat on bed or couch when resting. But even in lying certain minutiae must be taken into consideration. Some patients do not know how to rest, even lying down. They are constantly in motion, turning from side to side, restlessly changing their position. Or they constantly busy themselves in reading, writing, or talking. For such patients even lying down is exercise, and not the best form of exercise. The full benefit of the recumbent position can be attained only if the patient is taught to practise lying perfectly still with relaxed muscles.

It is unfortunate that the term relaxation smacks of dilettanteism in medicine, having been used in the Delsarte method, for the procedure is one of value if thoroughly understood and faithfully practised. It was pointed out long ago by Charles Darwin,* quoting Herbert Spencer, that the nervous energy liberated in mental activity overflows upon the muscles and, if in large amounts, upon the viscera. The mental activity of the subject can be determined in a rough way by inspection of the face, the expression of one in deep thought having a tenseness which is absent in revery or mental relaxation. Much more evident are the changes in expression when the emotions are excited. It is very easy to see that the face you watch denotes anger, grief, or joy, the tension of the facial musculature varying with the emotion felt. We judge of the nature of the emotion by the action of the small and unimportant facial muscles which are but little controlled by the will, but the overflow is not limited to these groups. The infant expresses his joy by waving his arms and kicking his legs. As he grows older he learns by degrees to express emotional display in the voluntary muscles which are well under his control, but more or less tension still exists. Furthermore, the viscera also are specifically affected by the varying emotions. Stimulation of the tear gland with its unimportant secretion of salt water discharged outside the body furnishes a safe means of minimizing the repercussion of emotion upon the viscera. The sthenic emotions raise the blood pressure and strengthen the heart action; the depressing emotions have the opposite effect. Anger is injurious to the liver; nervousness causes a polyuria, fear strengthens peristalsis with resulting diarrhea or even vomiting. The relation of the emotions to the genital organs is also a conspicuous illustration of nervous overflow.

The converse of the above proposition, namely, that the absence of tension of the muscles has a tendency to quiet the emotions and to inhibit the general activity of the brain as an organ of thought is not so easily proved, but seems to be shown by experience to be true. There is no better means of securing sleep than to relax com-

*Expression of Emotion in Man and Animals, 1873.

pletely all the voluntary muscles. The method is as follows: Assume a comfortable position with the body so placed that it is in a state of stable equilibrium; that is to say, is not maintained in its position by muscular effort, the arms and legs being likewise so disposed that muscular relaxation will not change their position. These precautions will prevent the "startings" or reflex contractions which so often disturb the body which is relaxing in its first sleep. Then give the attention to the relaxing of any muscles that are in a state of contraction, devoting especial attention to the muscles of the neck. Very often it will be found that the position thought to be one of rest has only been maintained by the contraction of groups of muscles, which when they relax cause the nose to plunge into the pillow or otherwise necessitate a change of position. The best way to relax the muscles is to expire deeply, letting the muscles go during the process, "hitting the bed hard" as the saying is, then holding the position gained in the following inspiration. There is an analogy here with the method of exploring the abdomen by pressure during expiration which is obvious. The classical position for relaxation is supine at full length with arms and legs everted, the stronger flexors thus being stretched to their full length, the weaker extensors being less likely to maintain involuntary contractions, but the principle in either position is of course the same. This procedure will seem to many a trifle unworthy of consideration, but nothing is a trifle which will exert a favorable influence to however slight a degree through weeks and months, and it is precisely the failure to take advantage of the seemingly little helps which makes the difference between success and failure in the treatment of tuberculosis. The patient having learned to relax for a few minutes—and it is useless to expect more at first—is encouraged gradually to increase the length of the time during which relaxation is obtained, being charged to seek perfect relaxation for a comparatively short time rather than to practise it carelessly for a longer period. Having learned the art, it is best to require him to devote to it certain periods of the day, preferably before meals, for as long a time as it can be endured without becoming burdensome. Patients differ much as to their success. Some succeed almost too well, so that they drop to sleep at every opportunity; others, taking it up half-heartedly, never really acquire the method. But the relaxing of the muscles is only the beginning of the schooling of the patient. He must be taught likewise to control his emotions. The influence of worry, homesickness, and other depressing emotions upon the nutrition is a familiar fact. The patient must be instructed to put away resolutely such depressing thoughts, at first during periods of relaxation, later at all times. To such counsel the obvious retort is: "I know that I am sick, miss my friends, etc., and it is useless to pretend the contrary." This is true, but the proper answer here is: "It does not matter what you know, so long as you do not allow it to excite your emotions. Your stomach does not care what you *know*, it is only disturbed when you *feel*." The idea that it is the emotional reaction to unpleasant ideas that is

injurious, not their intellectual apprehension, is one more easily imparted to the intelligent patient than might be supposed at first sight. For those who do not readily yield their consent to this psychic training it is well to suggest that, if they must worry and feel "blue," they select certain hours of the day as "worrying hours," in which they may feel as despondent as they please. The suggestion rarely fails to excite a smile and it is quite evident that an emotion deliberately excited at a fixed hour will rarely be strong enough to be prejudicial. It is well also to incite the patient to suggest to himself sensations of comfort and well-being, especially during the periods of relaxation. We physicians are far too prone to neglect the influence of unfavorable suggestions upon the well-being of our patients. The fact of sickness, one's presence in a sanatorium, physical examinations, discussion of symptoms, etc., are so many suggestions of an unfavorable kind. It is our duty to train our patients to feel that their salvation lies in securing a preponderance of favorable suggestions, that here again though one really does not feel well, yet if he can hoodwink his viscera into the idea that he does, he is accomplishing something worth while. Just as the intellectual apprehension of the fact of illness does no harm when divorced from the emotion reaction to the same unpleasant fact, so a more or less feigned sense of well-being does good though the intellect perceives its falsity; moreover, the feigning of a sense of well-being is the best way to realize a genuine sensation of the same kind.

The tuberculous patient is neurasthenic; that is, he has a weakened nervous system. Wundt long ago showed that if the sciatic nerve of the frog's leg is stimulated by an electric current, the effect of the stimulation of the fresh nerve is to produce, first, an inhibition of contraction, with continued action; later, a contraction of the muscle. But when the nerve has become exhausted by repeated stimulation the inhibition is absent and the first effect of the current is contraction. In other words, excessive irritability of the nerve is a sign of nervous exhaustion.

Similarly, the nervous system shows its weakness by a too ready yielding to emotion, a too rapid response to stimulation, a tendency to expend energy to the impoverishment of its store. Hence it is said that the neurasthenic have anesthesia of fatigue. A stimulus which would remain unnoticed by the healthy sets the nervous "on edge." A healthy man has no tendency to expend energy except for adequate reasons, the exhausted nervous system expends energy with extravagance on slight or no provocation. The restlessness of the sick is felt as well by the overfatigued. They are "too tired to rest." So the neurasthenic keeps up his activities to the point of exhaustion, and often prides himself upon an activity of mind and body which is overdrawing his capital. A patient will often claim with pride that he has a too active mind because unable to quiet his brain, though its activity is employed to no useful purpose. He may also be too "active" in his own estimation to need bodily rest. When a patient, after working beyond his strength, or at the end of long journeyings, is at last put to bed, the nervous excitement

which has kept him up abates and he begins to realize his true condition of weakness. He sometimes misinterprets this and believes that rest in bed, instead of revealing his weakness, is causing it. Not uncommonly he will demand to be allowed to leave his bed, declaring that he is growing weaker every day and will soon die unless he gets up. No time should be lost in explaining to the patient the need of rest and the reason why he has not apprehended that need. Complete rest with relaxation of the muscles is an imperative indication; the patient must learn at the earliest moment what his weakness really is, and, as it were, build up strength from a solid foundation. Having recreated in some measure his energy, the next problem is to persuade him to store it up. The overirritability of the nervous system does not disappear in a day. The patient is impelled to expend his minimal quantity of energy as soon as it is created. Whereas he much needs a bank account, he acts like the child who must spend his penny as soon as he receives it. The patient most difficult to control is he who has not experienced an exhaustion, the existence of which could not be denied. The thoroughly exhausted patient does not forget his experiences and is taught by them to appreciate considerations like the foregoing. But the patient who is simply "nervous" and restless requires much patient endeavor to bring him to a realization of his need of absolute rest. In fact, the best thing that could befall him would be an accident like a fracture, which demands long rest without any question. The history of a patient of the writer will best illustrate the fact that conditions which call for unusually prolonged rest often operate to the ultimate great advantage of the patient. A naval officer, fifty-eight years of age, had a rather large and active tuberculous lesion, involving the right upper lobe. There was sometimes rather high fever, but this abated under rest and he became able to take some exercise without apparent ill effect, except that cough and positive sputum persisted. The patient and his family were under the impression that an active life was to be desired and by rides and walks he fancied that his condition was improved. The probable outcome of the case appeared to be a considerable prolongation of life without absolute arrest of the tuberculosis. But, fortunately for him, a complication, usually regarded as serious, declared itself. His activities began to be impeded by pains which he ascribed to rheumatism and treated ineffectually in various ways. Finally the severity of the pain drove him to consult the writer, who at that time had not been in direct charge of the case. It then appeared at once that he had the classical signs of Potts' disease, with a well-marked "knuckle" over a dorsal vertebra. The prominence of the protrusion, the severity of the pain, and, above all, the fact that when attempt was made to apply a cast the pain shifted from one to the other side of the body led to the diagnosis of such a breaking down of the vertebra that the spinal cord was in danger of compression. The attempt to use a cast was therefore abandoned and the patient was put to bed on his back. There he remained, without once turning on his side, for seven months.

At the end of this long period, when he finally arose, his spine was soundly healed and the disease of his lungs was completely arrested. This happened twelve years ago. The patient is still on duty and in excellent health. There can be no doubt that the spinal complication was the most fortunate event that could have befallen him so far as the cure of the pulmonary condition was concerned.

The treatment of tuberculosis as thus outlined is not an easy treatment. It is well, therefore, to train the patient from the outset to feel that he has a responsibility for the outcome, that he must learn to exercise control over his nervous system, that the treatment involves a discipline which is not easy to acquire. The following case illustrates what may sometimes be accomplished with an intelligent and docile patient. An officer of the army arrived at Fort Bayard upon a litter, after a long journey, in such a state of exhaustion that death appeared imminent; in fact, his mother was at once sent for to be with him at the last, and stimulation was resorted to in the hope of keeping him alive until she could arrive. The case was one of acute involvement of the entire right lung. There was an enormous cavity, and the fever was high. In short, the case was one that seemed inevitably destined to death. The patient requesting a prognosis, he was told that he was very ill and that no promise of recovery could be given, but that there were certain things that he could do to help himself, and that they were worth trying. The psychic treatment was thereupon explained to him. He grasped the idea quickly and devoted himself to its realization with his whole soul. The result was that his mother, who came to see him die, remained at his bedside for two years. When he was finally able to leave his bed no one who saw the rosy face and well-rounded limbs of the patient would have dreamed that he had lost practically the whole of his right lung. He is still living after twelve years, is married, and at last accounts was in good health. If the skeptic doubts the connection between the brilliant outcome and the method of treatment, the writer can only rejoin that he has never seen so ill a patient recover, nor has he ever known a patient to carry out so thoroughly and persistently the principles of treatment inculcated.

The thought of spending endless days in bed, without occupation, is terrifying at first. But it is surprising how quickly the docile patient learns to adapt himself to the situation if the issue is squarely presented to him at the outset. The psychic training gives him occupation and in favorable cases the manifest benefit therefrom encourages perseverance. It helps greatly to have a schedule of work for the day, so many minutes or hours for muscular relaxation, succeeded by reading or listening to reading, perhaps writing letters, the care of the toilet, etc., then another period of relaxation, and so on, but always with the idea that the rest is the serious work of the day, its interruption the less frequent and prolonged periods of amusement. And so the patient soon learns to spend his days in a kind of busy idleness which makes them seem not long. Much depends upon the persistence and robustness of

view of the physician. If the latter indulges in an injudicious sympathy, tries to amuse the patient, teaches him to depend on outside helps instead of upon himself, not much will be accomplished. In short, the patient must be made to feel that the physician really believes in what he teaches. The patient must be taught the necessity of not interrupting the treatment on any excuse. The tubercle bacillus has no "days off"; he must, therefore, take none himself.

Fresh Air.—Rest must be by all means associated with the outdoor life so far as is practicable. Fresh air is perhaps as important a factor for the cure as rest, in the long run, but the difference between the air of a well-aired room and the outer air is not great enough to justify loss of rest or the endurance of discomfort in order to obtain the latter; a very ill patient is not strong enough to endure the vicissitudes of the outdoor life and does better in his room with windows raised. A stronger patient will profit by sleeping out of doors the whole or the greater part of the year; but no patient should be permitted to defy the storms and thus run the risk of becoming wet and chilled. A certain amount of hardening is advisable. Covering should be rather light than heavy. Warmth which leads to perspiration is always bad. For the same reason hot-water bottles should be used sparingly and for brief periods, and so-called chest-protectors should be eschewed altogether. As in the case of rest, it is important that the patient should feel that the physician is in earnest in his advocacy of fresh air. This he will not believe if he finds that he is permitted to stay in ill-ventilated rooms or even sit behind the stove in a room filled with tobacco smoke. Strictness of discipline in this regard is of much importance.

Exercise.—The febrile tuberculous patient in whom the maximum daily temperature habitually exceeds 99.5° F. should unquestionably be kept in bed. As the temperature falls the patient may be allowed to attend to his own toilet, perhaps shave himself or walk about a few minutes. Such relaxation of the regimen should occur immediately after eating, in order to take advantage of movement as a stimulation to peristalsis. It is better to permit alternations at first only between lying in bed and walking or standing than to allow much time to be spent in the sitting posture even without walking. These indulgences should be carefully specified, their duration prescribed and increase in length made very gradually under control of the temperature by repeated thermometric observations. The question as to the importance and significance of minor fluctuations in temperature is a most difficult one to decide. The temperature of a normal man who is left in bed continuously for weeks shows fluctuations of a fraction of a degree from very slight causes, as interesting studies have demonstrated. In these studies the temperature of normal men at work was also taken, night and morning, during a month, with the result that temperatures above 99°—99.2°, 99.3°, even 99.5°—were not uncommon in the evenings. The temperature which, taken before breakfast after a night's rest, was perhaps 97.8°, after half an hour's work habitually rose about 1°. The members of the group studied in

this way four years ago have all remained well. The fluctuations of temperature while perhaps not, strictly speaking, an entirely normal phenomenon, were at least not evidence of a masked tuberculosis. It is therefore unsafe to regard minor fluctuations of this kind an evidence of tuberculosis in doubtful cases without careful regulation of the mode of life. The well man may show considerable fluctuations, but they are developed in the course of an active life with its irregularities as to expenditure of energy and as to amounts and character of food consumed. If, on the other hand, the tuberculous patient is shielded from vicissitudes and leads a regular life, similar changes of temperature may rightly be ascribed, as a rule, to the tuberculous process *per se*. The problem, however, remains one that will frequently tax the acumen of the physician. The best rule is to require the acute case to rest irrespective of temperature, as the conditions become more chronic, to be guided strictly by the thermometer, and when the case has become one that is progressing toward arrest to ignore the slighter fluctuations of the temperature. Cases with large lesions must be treated with more severity as respects the enforcement of quietude than those with small lesions. All of which goes to show the absolute necessity of an accurate diagnosis of the patient's condition in every respect if one is to gauge with correctness the indications for rest or exercise, and, if the latter is permitted, its amount. Each case must be the subject of special study. No hard and fast rules as to fluctuations nor as to thermometer readings which permit exercise can be laid down. In case of doubt it is always safer to err on the side of too much rest. Exercise as a therapeutic measure should be restricted to the chronic case and the physician should be quite sure that he is able to determine the fact of chronicity before making such prescriptions. The writer has sometimes had occasion to reproach himself for undue leniency in permitting exercise prematurely. The error most frequently made is to allow the amount of exercise to be too rapidly increased and to fail to insist upon adequate control of the effects of exercise by the thermometer. As has been well said, the patient who begins to exercise has reached a period of danger in his course of treatment. He can hardly be too carefully watched. In the Southwest are the graves of many consumptives who have been told to "rough it and keep away from doctors."

Feeding.—The patient who has worked beyond his strength has often been too tired to eat for long periods, in some cases has had little and poor food. Put such a patient to bed, with a mind free from care, and give him an abundance of good plain food, and it is surprising how much he can eat and how well he will digest his food, gaining weight rapidly and improving unmistakably in general condition. In a case of this kind, where there is a deficit to make up, the problem of nutrition is easy—all that is necessary is to give the patient what, and as much as, he wants. When cases from the proletariat of large cities are admitted into tuberculosis institutions for comparatively brief periods, a few months at most, the great majority of the patients will be-

long to the class which is able to eat well and will be benefited by so doing. Hence has arisen the teaching that a patient should be overfed, that hyperalimentation is one of the factors of treatment. So it is, so long as there is a deficit of nourishment to be made up. He who has starved long can feast for a while with impunity. But if such a patient remains long under treatment the time will come when he is "filled up," as the saying is. He has made up his deficit and from that moment he becomes like others as respects the dangers of surfeit. Many patients have always had an opportunity to rest and an abundance of good food to tempt their appetites. They have no true deficit to make up. For such patients stuffing with food is only prejudicial. In many cases difficulties of digestion are dependent upon the kind rather than the amount of food. Too much of concentrated foodstuffs, acids, sugars, fats, and meats, tax a system not stimulated by exercise and produce heaviness, gastric acidity, and bad-temper. The stomach and intestines of him who lies still all day, if kept over full, become enfeebled in their peristalsis and dilatations readily occur. The food consumed at one meal should be entirely digested before the next meal. It is a common fault to overfeed from a sense of duty, with no real desire for food. The patient who begins the day with a too ample breakfast often makes that breakfast his only meal. It is often wise to omit a meal or two until a healthy hunger develops. He who is a little ahead of his needs is never hungry, he who does not quite satisfy his appetite always enjoys eating. There is truth in the saying, "It is better to eat yesterday's dinner than to-morrow's." In view of the prevalent doctrine of the need of overfeeding in tuberculosis, it may be well to cite a case in which the cure of tuberculosis progressed, though the patient was on what might be called starvation diet. An officer returned from the Philippines with small tuberculous lesions of both upper lobes. The sputum was positive for tubercle bacilli. In addition to the tuberculosis he had tropical sprue, and had had hookworm. Upon arrival he was unable to eat anything for many weeks except small quantities of milk. To this he was finally able to add a small quantity of grapenuts and very gradually to increase his food supply by an occasional egg, a few biscuits, a ripe pear, etc. Notwithstanding the fact that his diet for months was greatly deficient, both in calories and in nitrogen, his tuberculosis progressed most favorably to complete arrest. He finally recovered entirely from the sprue, and has been on duty in the Philippines for six years.

The fact that semistarvation does not necessarily lead to tuberculosis, as is commonly believed, has been demonstrated on a large scale in the case of the French prisoners. The alarming accounts as to the prevalence of tuberculosis among these unfortunates, which have received universal credence, are now found to have been greatly exaggerated. In certain groups of returning prisoners the percentage of tuberculosis has been rather high, but among large numbers returned of late it is reported to have been surprisingly low.

Symptomatic Treatment.—The symptomatic treatment of the consumptive does not differ from that of other patients. Cough medicines should be used sparingly and only for special indications, as, for example, after hemoptysis. Much can be done by teaching the patient to suppress useless cough. The patient who has a cavity should be taught to empty it, at least once a day, by assuming a position that will favor drainage into the bronchi. Some patients have the idea that it is necessary to expel expectoration at the earliest possible moment and often exhaust themselves by prolonged coughing in order to raise an insignificant pellet of mucus, which, with a little patience, would have been forwarded by the natural mechanism so as to be readily ejected with little effort. The idea that expectoration is infectious for the patient and must be gotten rid of without delay is one for which the physician is sometimes responsible. A worse error is to inculcate the notion that it is extremely dangerous to swallow sputum. Patients are sometimes kept in a state of nervous apprehension, which is most prejudicial to their recovery by such injudicious teachings.

The tuberculous patient ascribes all his unpleasant sensations to the tuberculous process. For him the pain in the chest which is so common, always means pleurisy and a little diarrhea raises the specter of intestinal tuberculosis. The physician can be of much comfort by teaching that the fugitive pains in various parts of the body, and the various manifestations of indigestion, are common in all those whose health is below par and have no direct connection with tuberculosis. At the same time such symptoms call for inquiry as to the cause with a view to improving the personal hygiene and the patient should be encouraged in the ambition so to regulate his life as to have as nearly perfect digestion and elimination as can be attained under the conditions.

Tuberculin.—The writer has seen too often very serious harm from tuberculin as employed by others, to be enthusiastic concerning its use. Tuberculin is most helpful to those who need help least. Advanced cases of tuberculosis are very seriously injured by it, but the rather numerous class of sanatorium patients who have little or no active tuberculosis, their disease being of a chronic, though often diagnosticated as acute type, are able to tolerate it, sometimes apparently to their advantage. Those physicians whose practice is mostly confined to cases of well-marked manifest pulmonary tuberculosis are rarely enthusiastic advocates of its use. An accurate diagnosis is indispensable. Tuberculin in the hands of the ignorant is a terribly deadly weapon. The writer believes that cases of genuinely active tuberculosis are more often harmed than benefited by it and is of the opinion that better results in the long run for the average patient are attained by the psychic treatment. He is, therefore, opposed to the use of tuberculin in army hospitals.

^a *Carabelli's Tubercle in Antiquity.*—Jeanselme has found this supposed stigma in the teeth of subjects in all periods of history and pre-history and from all countries. This discovery greatly lowers the worth of the claim that it is very largely a stigma of inherited syphilis.—*La Presse Médicale.*

STAMMERING.

By AUGUST J. P. PACINI, M.D.,

NEW YORK.

DIRECTOR OF THE MEDICAL LABORATORIES, AMERICAN TELEPHONE AND TELEGRAPH COMPANY.

STAMMERING is a transient hesitancy in pronouncing a vowel or a consonant, or in uniting a vowel with a consonant. Should the obstacle occur in the middle of a word, it often happens that the preceding letter or syllable is repeated several or many times, when the defect is known as stuttering.

Etiology.—The etiology or cause of stammering is the subject of much conjecture, and many superficial observers have supposed that they had discovered it, only to be disappointed upon further examination. In seeking the etiology of stammering, it is essential to consider any predisposing influence that may be exerted by the various factors associated with the defect.

Age.—Stammering is an affliction that belongs to youth. Makuen in a report of 1035 cases studied at the Philadelphia Polyclinic Hospital, states that it is rare for the affection to develop after puberty, and that 38 per cent of his patients asserted that they had stammered as long as they could remember. Sala, in his work, "Cura Della Balbuzie e Dei Defetti Di Pronunzia," states that stammering appears most usually between the ages of 3 and 9, rarely after puberty. The predisposition to stammer may be noted in some cases even before the child has learned to talk fluently.

Sex.—Statistics show that about 84 per cent. of the cases seeking relief are males, and this would seem to indicate that sex should be regarded as a factor contributing to the cause of the affection. Makuen attributes the prevalence of male stammerers to the more variable and unstable male cerebral speech centers.

It is a matter of incidental interest, perhaps deeper than a coincidence, that males suffer much more frequently from neurotic and psychoneurotic affections than females. Among school children, Goddard tested, by the Binet measuring scale, 1547 cases, and his figures, distributed over various age limits, indicate a lower mental status for boys than for girls.

Temperament.—A characteristic nervous temperament is typically dominant among stammerers. This condition may follow one of the infectious fevers or other diseases of childhood, or it may be the result of eye strain, hypertrophied tonsils, adenoid vegetations, or intranasal pressure from whatever source. Strong emotional tendencies, fright, timidity, fear, and a proneness to imitate or mimic are further temperamental characteristics of the stammerer.

Mentality.—Stammerers do not present, as a rule, any markedly abnormal mentality. An analysis of 1035 cases made by Makuen shows the following distribution: 85 per cent. average, 10 per cent slightly below average, 5 per cent decidedly below average. These percentages do not differ radically from those cited by Goddard in his report on the examination of about two thousand school children, comprising one whole school system.

Chervin, in his work "Le Begaiement, Sa Place Dans La Neurologie," expresses the view that in

most cases stammerers do not present an impaired mentality, and that any tendency toward mental dullness by them manifested is dependent upon their conscious effort to avoid embarrassment or ridicule.

Health.—The health of the stammerer is generally below par. Neuroses and psychoneuroses are prevalent in stammerers and their ancestors, and should be considered among the probable predisposing causes. Constitutional disorders are related to stammering only in so far as they are capable of reacting, reflexly, on the central nervous system.

Glandular enlargements in the pharynx and intranasal hypertrophies and spurs act as causal factors in so far as they interfere directly with the free automatic action of the muscles of vocalization and articulation. Such cases should be referred to the school medical examiner, and his counsel obtained.

Heredity.—Many authorities regard stammering as an inheritable defect. Denhardt, in his book, "Das Stottern Eine Psychose," claims in 1994 cases to have found evidences of heredity in 1545 stammerers, that is approximately 78 per cent. Wyneken says on the matter, "One cannot escape the fact that there exists in many cases a certain inborn disposition to stammering," and he adds further, "which cannot be eradicated by the most careful training." Makuen believes heredity to be the most important etiological factor. His figures are: 39 per cent. had relatives who stammered; 32 per cent. stammered through association (imitation); 28 per cent. dated stammering to an instant having received a sudden shock; 3 per cent of stammerers were the offspring of consanguineous marriages.

Davenport, in his "Heredity in Relation to Eugenics," gives pedigrees of two stammering families. When we consider that the combined observations of Denhardt, Makuen, and Wyneken were able to accredit, and without positiveness, an hereditary etiology in only 35 per cent. of 4231 cases, it detracts materially from the probability of Davenport's view, based on two cases, that stammering is to be regarded, hereditarily, as a unit character.

Doubtless many cases of stammering ascribed to heredity are in reality due to unconscious imitation; but where this explanation fails, heredity in its relation to the transference of a psychoneurotic diatheses, which, as we have noted, predisposes stammering, must be considered before one may definitely claim the existence of an hereditarily determinative stammering unit in the germ-plasm.

Stigmata of Maldevelopment.—Decided evidence of arrested or imperfect development, whether anatomical, physiological, or psychical, are unfailingly present among stammerers.

High and irregular palatal arches, palatal growths, bifid uvula, atrophied or hypertrophied velum, and hypertrophied ligular frenum are the chief anatomical stigmata to be found among stammerers.

Nystagmus, asthenopia, strabismus, astigmatism, and partial deafness are important physiological stigmata.

Immoral habits of life, manias, hallucinations, illusions, and tendencies toward hysteria, melancholia, epilepsy, and dementia are the frequent psychical stigmata encountered.

Mental Type and Primary Cause.—Adopting the

nomenclature of Charcot as regards the types of mental imagery determining thought, we have: (1) The visile. (2) The audile. (3) The motile. The visile remembers best that which he sees; the audile, that which he hears; and the motile, that which he feels. The prerequisite of voluntary speech is a definite antecedent mental verbal image, be it visile, audile, or motile.

Failure to transfer an antecedent verbal image, once formed, to the nervous mechanism of speech, is aphasia. We shall not concern ourselves with aphasia at this time. Incapacity to form an antecedent verbal image, is amnesia.

Secondarily, the age, sex, temperament, mentality, health, heredity, and stigmata of maldevelopment are contributory factors that assist in the undue irritation of the psychologic qualities whence amnesia arises.

Primarily, stammering results from a transient amnesia which temporarily inhibits the arousal of the necessary antecedent verbal image, of whatever type—visile, audile, or motile.

Derangements Accompanying and Resulting from Stammering.—The derangements accompanying and resulting from stammering and stuttering may be divided into two groups: (1) Psychologic. (2) Physiologic.

Psychologic.—In common with the physical manifestations of all psychoneurotic affections, stammering and stuttering may, and usually do, give origin to secondary psychic disturbances. A general hypersensitiveness to suggestion is the predominant secondary disturbance occasioned by stammering, and through this channel, mimicry and association exert their cogent effect upon the psychic mechanism involving amnesia.

Physiologic.—Physiologically, the derangements accompanying stammering and stuttering may be classified as to (1) Respiration, (2) Vocalization, (3) Articulation.

Respiration expresses two distinct ideas. On the one hand, it may mean the entrance of oxygen into, and the exit of carbon dioxide from the individual; on the other hand, it may have reference to the visceral, that is, muscular and pulmonary, movements by which these gases are caused to flow in and out of the lungs.

Inspiration is the process brought about by certain muscles, which by their action enlarge the thorax and involve the diaphragm, abdomen, and costal appendages. At the end of inspiration, the various muscles relax, and combined with an active recoil of the lungs, which have been stretched during inspiration, the thorax compresses and expels the air. Eupnea is a condition of normal easy breathing. Dyspnea, difficult breathing; apnea, suspended breathing; hyperpnea, increased respiratory activity; polypnea, deep, labored breathing; and asphyxia is the condition of convulsive breathing followed finally by infrequent and feeble respirations.

Depending upon the severity of the case, or the time of duration of the transient amnesia, the stammerer may present any of the gradations of abnormal breathing from dyspnea, apnea, hyperpnea, polypnea to asphyxia, in which latter case the heart beats are less frequent, the blood-pressure is increased, the skin may become congested and red,

or bluish, the lips and gums become cyanosed, and in rare cases consciousness is temporarily lost.

Another type of respiratory defect which is not uncommon among stammerers, is the attempt to vocalize at the end of expiration or the beginning of inspiration. There being no air with which to vibrate the vocal cords for the production of voice, the stammerers' attempt to speak results in a temporary aphonia, or absence of voice; and their failure to produce speech reacts detrimentally upon their psychic amnesic center prolonging the amnesic period, and therefore the stammering interval.

Derangements of vocalization may occur in one or two ways: First, by an affection of the exceedingly complex nervous mechanism of afferent and efferent fibers that run to and from the cortical centers controlling the voice. Second, by affections of any of the anatomical parts concerned in the mechanical production of sound.

Disturbances involving the nervous mechanism of the voice belong to the consideration of aphasia; but where the psychoneurosis is the product of stammering, the nervous mechanism of voice may become involved secondarily, and the two neuroses act, circumfluently, with corresponding speech interference.

Communicating with the trachea below, and the pharynx above, the larynx, holding the vocal cords, is the seat of vocalization. The vibration of the cords produces a sound which is intensified by reinforcement of the vibrations, by the resonating cavities above and below their insertion.

Disturbances of the voices may be referred to any of the three features of voice, which are: (1) Intensity, (2) Pitch, (3) Quality. The intensity depends upon the amplitude of vibrations of the cords. Hypertonicity of the muscles regulating the stretching of the cords produces an abnormal intensity. Cancerous growths on the vocal cords have been demonstrated not infrequently; and their effect on the intensity markedly noted.

The pitch of the voice depends upon the number of vibrations that are produced in a unit of time. The thickness, tension, and length of the cords determine the pitch of the sound produced; and any abnormality of the thickness, tension, or length is manifested by an unusual pitch. The quality of the tone depends upon the character of the upper partial tones which are combined with the fundamental tone. These are varied by the alterations in the shape or size of the buccal, nasal, and pharyngeal cavities. It is self-evident what the effect of adenoid vegetations, hypertrophied tonsils, stenosis of the nasal cavities, palatal defects, and similar abnormal growths and formations of the resonating cavities will be.

The derangements of articulation, like the derangements of vocalization, may be of nervous or anatomical origin. Interference with the nervous supply of the tongue, the lips, the velum or soft palate, or to the facial muscles involved in the mechanical setting of the letter sounds may act reflexly on the cerebral speech centers with sufficient intensity to produce amnesia. More often, the amnesia affects the nervous supply of the articulatory organs. This is accomplished by the combined effect of the many periods of anarthria, or suppressed articulation which the amnesia institutes.

As to the anatomical derangements of articulation, the vowels being laryngeal sounds, any defect in their formation is to be found in the larynx, or secondarily in the malpositions of the tongue due to anatomical deformity of that organ or to nervous affliction, like unilateral paralysis of the same; whereas, in the case of the consonants, anatomical derangements are sought in the particular organs that are used in the formation of the labials, labiodentals, linguodentals, anterior linguopalatals, or the posterior linguopalatals. Since the names of these consonant groups indicate the region of the mouth in which they are produced, and the means by which the air blast is interrupted, it is superfluous to repeat the various anatomical entities that are apt to be deranged in their malproduction.

Wyllie, Bastian, Gutzmann, and their contemporaries adhere to the theory of causality of stammering announced by Dr. Arnott in 1827, wherein the inability to produce voice is designated as the fundamental cause of stammering.

If the difficulty lay primarily with the inability to produce voice, all traces of the impediment should disappear when the stammerer whispers, for in whispering the voice is not involved. The general experience to the contrary is sufficient to refute the validity of this theory.

Similarly, defects in articulation and respiration have, at various times and by numerous writers, been considered as primary causes of stammering and stuttering. As in the case of delayed vocalization, the unsoundness of these views is evident.

There can be no doubt that remedial methods of phonation based on these theories do afford varying relief; but stammering is not a defect of phonation. Phonation is simply a physical manifestation of the defect of stammering; and, as we shall see later, the most permanent and the most satisfactory results in the treatment of stammering are obtained when the primary transient amnesia is recognized, and the remedial measures aimed at the removal or obliteration of the same.

Diagnostic Examination.—We must never lose sight of the fact that neither in a normal nor a pathological sense is there any mental activity which is not dependent on the central nervous system. The faculty of speech is presided over by delicate and complicated cerebral areas inciting to action and working in harmony with peripheral organs having other important bodily functions in addition to those of voice and speech production. A particular type of stammering or stuttering, therefore, having its origin in a defective action of some of these important central areas and peripheral organs, necessitates, for the better understanding and the scientific handling of the case, a minute investigation into the condition of each of the twelve cranial nerves.

Without attempting to describe the details of the methods for testing the functioning of the cranial nerves, we shall enumerate the deranged conditions and the manifestations of the derangements with a view of noting the underlying relation between imperfect nerve action and stammering.

From this tabulation, two features stand out pre-dominantly. First, the relation of the cranial nerves to the definiteness of the mental type; second, the relation, from the physiological standpoint, that

deranged function bears to the mechanism of the organs of speech. This latter item is especially manifest in the cases of the glossopharyngeal, vagus accessory, spinal accessory, and hypoglossal nerves.

Nerve.	Condition.	Manifestation.
1. Olfactory.....	Anosmia.	Partial loss of smell, bilateral or unilateral.
2. Optic.....	Amblyopia. Anisometropia. Hyperopia. Myopia. Astigmatism.	Partial loss of vision. Formation of imperfect retina images. Far-sightedness. Near-sightedness. Refraction errors.
3, 4, and 6. Motor oculi, patheticus, abducens.....	Orthophoria..... Heterophoria. (a) Esophoria. (b) Exophoria. (c) Hyperphoria.	Perfect binocular vision. Imperfect binocular vision. Inward deviation. Outward deviation. Upward deviation.
5. Trifacial.....	Sensory anesthesia. Motor paralysis.	Injury to sense of touch. Difficulty in chewing.
7. Facial.....	Emotional expression.	Unilateral or bilateral facial paralysis.
8. Acoustic.....	Deafness.	Impaired air conduction. Impaired bone conduction.
9. Glossopharyngeal....	Loss of pharyngeal reflex.	Nasal regurgitation of liquids.
10. Vagus accessory....	Pharyngeal. Laryngeal.	Inability to swallow. Change or loss of voice.
11. Spinal accessory.....	Palatal paralysis.	Non-movement of velum.
12. Hypoglossal.....	Lingual paralysis.	Modified articulation. Deranged mastication. Impaired deglutition.

Next in order, the diagnostic examination should be directed to the elicitation of the mental type of the stammerer. To this end, the modern methods of psychophysics, or of physiological psychology, are sufficient.

It should be recalled that the results of the cranial nerve examination afford a general indication of the mental type of stammerer; so that in most cases it is superfluous to conduct the routine psychophysical investigation in full.

The kinesthetic and static senses play an important part in the perception of space, besides furnishing data for the perception of the positions and motions of our members and bodies as a whole. To discern the motile, or kinesthetic mental type then, it is only necessary to direct investigation along the following kinesthetic line:

1. *Muscular Sense*—(a) Lifting moderate weights. (b) Discriminative sensibility for lifting weights (Weber's Law). (c) Adjustment of the motor discharge.

2. *Inervation Sense*—(a) Simultaneous movements. (b) Illusory movements of immovable members.

3. *Sensations of Motion*—*Joint Sensation*—(a) Passive elbow motion. (b) Location of movements.

4. *Sensations of Resistance*—(a) Illusory resistance.

5. *Bilateral Asymmetries of Position and Motion*.—(a) Apparently asymmetrical motions of the arms.

6. *Recognition of the Body as a Whole*.—(a) Recognition of direction. (b) Vertical and horizontal positions of the body.

7. *Sensations of Rotation*.—(a) Perception of uniform rotation. (b) Illusion of backward rotation. (c) Location of the organs for the perception of rotation.

8. *Sensations of Progressive Motion*.

Having completed the kinesthetic sense inquiry, we now explore the auditory or hearing sense. This is accomplished somewhat along these lines:

1. *Sounds in General*—(a) Minimal sound. (b) Discriminative sensibility for the intensity of sound. (c) Auditory fatigue. (d) Inertia of the auditory apparatus. (e) Noise.

2. *Single and Successive Tones*—(a) Highest tones. (b) Lowest tones. (c) Recognition of absolute pitch. (d) Just observable difference in pitch. (e) Pitch distances. (f) Recognition of musical intervals.

3. *Simultaneous Tones*—(a) Beats. (b) Combination tones. (c) Blending of tones. (d) Compound tones. (e) Timbre.

4. *Binaural Audition and the Location of Sounds*—(a) Unison tones heard with two ears. (b) Beats heard with two ears. (c) Judgments of the direction of sound. (d) Intercranial location of sounds. (e) Location of the tones of tuning forks pressed against the head.

Finally, the eye mechanism and vision in general are investigated as to the visual sense. This includes:

1. *Retinal Images and Accommodation*—(a) Retinal image. (b) Accommodation. (c) Accommodation image. (d) Mechanism of accommodation.

2. *After-Images*—(a) Accidental or consecutive. (b) Positive after-images. (c) Negative after-images. (d) Sequence of colors.

3. *Movements of the Eyes*—(a) Reflex movements. (b) Associated movements. (c) Actual movements. (d) Convergent movements. (e) Involuntary movements.

Having concluded the psychophysical examination of the stammerer, we are now informed as to the mental type which he represents.

Completion of the diagnostic routine includes the noting and recording of whatever anatomical or physiological derangements the stammerer presents.

By anatomical derangements, reference is made to abnormal formations or growths. Perforated palate, or adenoid vegetations are typical examples of the anatomical derangements.

By physiological derangements, we refer to the functional abnormalities through which stammering is made manifest. Imperfections of articulation, respiration and vocalization are the typical physiological derangements.

The diagnostic routine, then, if properly carried out, affords us the following information: (1) Status of the central nervous system. (2) Mental type of the stammerer. (3) Anatomical and physiological manifestations of the defect.

The information gained by a scientific, systematic survey after this scheme places us in a better position to localize accurately and to attack effectively the stammering evil.

Remedial Measures.—Most systems of treatment consist of exercises and expedients that are presumed to give one control of the refractory organs, or to regulate in some way the aberrant function. The basis of such systems is the prevalent view that stammering is a physiological defect, and that its cause lies in some respiratory, articulatory or phonetic anomaly.

There can be no doubt that in the majority of cases, systems of respiration, articulation, or phonation render valuable assistance in remedying stammering; but where this occurs, it does so not for the physiological benefits that the systems impart,

but for the psychological effect that they bear on the child.

To eliminate useless and endless repetition, the most practical presentation of the subject of the treatment of stammering will be to describe the units without necessary reference to the systems in which they occur.

Respiratory Measures.—Respiratory disturbances are often attributed to weak nerves or to muscular spasms. Gutzmann, Chervin, Findley, Shuhlman, Behnke, and Kreutzer are the foremost exponents of this view.

Respiratory disturbances are treated by breathing exercises which have for their object the strengthening of the respiratory muscles and the establishment of conscious control of the expiratory stream.

Systematically arranged, the breathing exercises involve various combinations of inspiratory and expiratory movements, and periods during which the breath is held.

The following exercises may be regarded as typical of the average system where breathing exercises form a prominent feature:

1. Inhale through a period of two seconds, fully inflating the lungs.

2. Exhale through a period of two seconds, fully deflating the lungs.

3. Inhale similarly through a period of four seconds.

4. Exhale similarly through a period of four seconds.

5. Inhale through a period of six seconds.

6. Exhale through a period of six seconds.

7. Inhale through a period of eight seconds.

8. Exhale through a period of eight seconds, etc.

9. Inhale through a period of two seconds.

10. Exhale through a period of ten seconds.

11. Inhale through a period of ten seconds.

12. Exhale through a period of two seconds, etc.

13. Inhale discontinuously through a period of four seconds.

14. Exhale discontinuously through a period of four seconds, etc.

Endless combinations of these exercises have been devised. Many persons teach these exercises from charts in which the directions are conveyed by symbols. Inspiration and expiration are represented by vertical and horizontal lines, or dots and dashes, or squares and circles. Periods during which the breath is held are usually indicated by parentheses, figures in the parentheses indicating the length of the pauses. In class instruction the time is either measured by a metronome, or is given by the instructor, who leads the class with a baton or beats time with his hand.

In another type of exercises the various sets of breathing muscles—the chest muscles, the intercostal muscles, the dorsal muscles, are exercised separately. Some sort of procedure is often prescribed for giving one consciousness of the diaphragm.

Use of the spirometer, an instrument for measuring lung capacity, forms part of the equipment of some instructors.

Throughout the United States, breathing exercises are practised in connection with dumb-bell exercises.

Still another expedient of respiration control that one finds among English, French, and German workers, is reading in a whisper. Bell, in his "Principles of Speech," recommends this procedure as a simple breathing exercise.

Prescinding from further review of the respiratory exercises commonly employed for the treatment of stammering, it may be stated, without any reservation, that these exercises may furnish an excellent instrument for elocutionists in treating physical stammering; and in the hands of a competent instructor, physical stammering has often been eliminated in a surprisingly short period; but the primary cause of stammering, the transient amnesia, remains unaffected.

If one has unreserved confidence in any system, one is temporarily absolved from fear, bewilderment, and inhibitive autosuggestion; and for a time at least physical stammering is reduced; but since the primary cause persists, confidence may be lost at any time, and the secondary causes return.

While respiratory measures are superficially beneficial, their failure to eradicate the transient amnesia explains the relapses and recurrences of stammering among children who are discharged as corrected.

Vocalization or Phonation.—We shall now examine the common expedients relative to phonation that are considered efficacious.

It should be observed that one of the commonest views in regard to stammering is that the disturbance is caused by a failure of the voice. This is a truism. Stammering is a failure of the voice, and to the supporters of this view, Ashmann, Thorpe, Wyneken, Arnott, Muller, and Forbes included, the question should have been put, "What causes failure of the voice?"

Two general methods are followed in combating defective production of the voice. First is the training of the child in various exercises with a view to establishing voluntary control of the vocal organs. The other method is to practice the child in some special mode of utterance with the object of counteracting the supposed cause of stammering during actual speech.

Popular exercises for infixing consciousness of the movements of the entire larynx consist in the monotone pronunciation of the vowels and vowel sounds. The ascent and descent of the larynx are then pointed out.

Establishing the conscious control of the vocal cords is the purpose of Guttman's direct and indirect attack.

Inflection exercises are frequently resorted to for strengthening the muscles of the larynx, the vocal cords, and the glottis and epiglottis. These exercises are frequently practised from charts, rising and falling inflection being indicated by various arbitrary symbols.

The following sentences for the practice of inflection are typical:

1. John sold a horse.
2. John sold a cow and a horse.
3. John sold a bull, a cow, a calf, and a horse.
4. John sold a pig, a bull, a cow, a calf, and a horse.
5. John sold a sheep, a lamb, a pig, a cow, a bull, a calf, and a horse.

6. John sold a cow, not a horse.

Similar sentences are repeated *ad nauseam*, until John has sold all the live-stock of Noah's Ark.

A number of these exercises have been endowed with special names. Thus we hear of Expulsion and explosion, Expulsive and explosive stress, Tremor, Swell and stop, and a score of others.

Drill charts are often employed, and their complexity is augmented by various refinements and improvements; and in some cases musical notes, inflection signs, and intensity signs are included in the charts.

As in the respiratory exercises, the time is measured by a metronome or is given by the instructor who leads the class with a baton in his hand.

Systems of phonation are highly valuable for their psychological effect. Vocal exercises, when practised daily, may intensify the auditory imagery of the stammerer, and thereby exert a beneficial influence on speech; but if an auditory intensification of imagery occurs, it is temporary, and whatever speech improvement has accrued is likely to be lost when the exercises are discontinued.

Before leaving the topic of phonation, let us consider a few of the various measures that are supposed to obviate stammering when applied during actual speech.

An expedient popular for more than half a century is that of talking in a low-pitched voice. In support of this measure, the argument is advanced that a low-pitched voice requires relaxation and separation of the vocal cords, which argument would have been more or less sound if it had first been shown that stammering is caused by the lack of relaxation and separation of the vocal cords.

A similar measure is that of beginning a sentence in an unusually quiet voice.

Speaking in a monotone is recommended as a specific for stammering; and in contrast to this measure the expedient of using the entire range of the voice in a sing-song fashion.

Arnott's expedient was to prefix a short *e*, as in *berry*, to the first word of the sentence. This device, with its countless variations, has become quite prominent in the therapy of stammering. A more recent version of the formula requires the prefixion of the short *e* to every word in the sentence.

A variant of the above measure consists in prefixing the sound of the letter *n*, or *m*, to the initial word or to difficult words in a sentence. This ruse is already three-quarters of a century old, and its value is as questionable as that of the indefinite *e*.

Comment on the measures mentioned is unnecessary. Stammering is not a defect of phonation; defective phonation is but a physical manifestation of stammering; and it is as pernicious to attempt to relieve stammering through the correction of one of its manifestations, as it is to attempt to cure heart disease by feeding phenacetin or pyramidon to relieve the headache which is an index to the heart trouble.

Articulation.—When the cause of stammering is considered to be misuse or lack of control of the articulative organs, the corrective training usually consists of exercises for strengthening the speech muscles and rendering them subservient to the will, and of practice in articulating the various refractory consonants.

Considering first the exercises intended to produce muscular control and development, we find that labial exercises are deemed important. The following labial exercises are taken from various sources, and are typical:

1. Open the mouth wide, giving it its fullest extent longitudinally.
2. Do the same, extending it laterally.
3. Pout the lips, making a somewhat wide orifice.
4. Close the lips and let them remain closed without pressure.
5. Blow through the lips.
6. Blow through the lips with the cheeks puffed out.
7. Blow through the pouted lips.
8. With the teeth apart, draw up the lower lip between them.
9. Do the same with the upper lip.
10. Do the same, drawing in both lips.

Exercises similar to the following are sometimes recommended for the lower jaw.

1. Drop the jaw.
2. Protrude it.
3. Draw it back.
4. Move it to the right.
5. Move it to the left.
6. Go from one to the other of the above exercises.

Lingual exercises are popular with a number of instructors. As a type, the exercises recommended by Guttmann in his "Gymnastics of the Voice," have been widely followed by speech-specialists. They are too numerous to enumerate now.

Exercises for the soft-palate or velum are now and then encountered.

Most of these exercises for the articulative organs are doubtless of value as ordinary elocutionary measures. The jaw exercises are probably dispensable; while the soft palate exercises are valuable only when there is a tendency to nasality.

As in the cases of respiratory and phonetic exercises, charts and diagrams are resorted to in abundance.

A passing mention should be made of a few stratagems used for circumventing particular consonants and consonantal sounds.

1. The use of *oo* for *w*. Oo-aif, for waif. Oo-ill for will.
2. The use of *ee* for *y*. Ee-ou, for you. Ee-awn, for yawn.
3. The use of *kw* for *q*. Kw-ick for quick. Kw-alm for qualm.
4. The regeneration of *r*, as er. Er-rot, er-run, er-rat.

Concerning these stratagems, it may be said that *oo* requires the same position as *w*; *ee* requires the same position as *y*; *kw* requires the same position as *q*, for which letters they are substituted. The substitutions are self-evidently inconsistent; and should they prove temporarily effective they are still open to the criticism that they induce unnatural speech.

Mechanical Aids.—Resort to mechanical aid is occasionally recommended. Knotted towels and head bandages to keep the tongue in a high position; paper knives, buttonhooks, knitting needles, to correct faulty articulation; speaking with a mouth full of gravel, like Demosthenes, who, incidentally, was troubled with lallation, not with stammering; the

use of cork between the teeth; and many other mechanical contrivances and collections of machinery are still employed for the treatment of stammering.

Even the surgeon has had his hand in the treatment of stammering. The operating craze began in 1841, but like many of its victims it was blessed with an early death. The parent operation consisted in slicing a wedge from the base of the tongue, and subsequently sewing the gaps together. The filial operations consisted in removing adenoids, tonsils, elongated uvulas, and any other accessory material.

No intelligent person can contend that genuine obstructions to respiration should not be removed. Such obstructions are, however, seldom in causal relation to stammering.

Psychological Methods.—Among the psychological methods we find an accessory that has been in use for over a century. A period of silence at the beginning of the sentence. Sing-songing, time beating, and drawling are equally antiquated and futile. By sing-songing, any stammerer might drawl fluently from the beginning; but it is an open question whether the sing-songing is more pleasant to listen to than the stammering.

Hypnotism, a major psychologic procedure in the treatment of stammering, has failed so completely as to preclude the necessity of any consideration.

The most recent psychologic expedient is psychoanalysis, the purpose of which is to ascertain the obsessing fear. Lack of data prevents me from discussing this topic.

We have reviewed, in a cursory manner, the leading physiologic systems advanced for the treatment of stammering, which include systems of Respiration, Phonation, and Articulation.

Since respiration, phonation, and articulation are not in causal relation to stammering, it is manifestly unnecessary to repeat how trifling is their value in remedying that speech defect.

To correct stammering successfully, rapidly, and permanently, it is of paramount importance to eradicate its cause—the transient amnesia of whatever type.

From the results of the cranial nerve examination, and the psychophysics elicitation of the mental type of the stammerer, let us assume one of the possible diagnoses, stammering due to a transient auditory amnesia.

That means that the defect, in the case mentioned, is due to the recurring transient inability on the part of the stammerer to form the required antecedent audible verbal image necessary to normal speech.

The treatment, briefly, consists in re-educating the central nervous system, somewhat after the fashion connected with the name of Fraenkel, in such a manner that the antecedent verbal images are no longer auditory, but either visual or kinesthetic. This accomplished, the stammerer no longer depends upon his defective auditory sense for his antecedent speech images, but upon a new-formed, and more perfect, visual or motile sense.

In summary, the treatment may be divided into three steps:

1. Determine the status of the central nervous system for the purpose of finding a more perfect sense to replace the defective one of the stammerer.

2. Determine the mental type responsible for the stammering defect according to the psychophysics examination suggested.

3. Re-educate the stammerer in a new mental imagery, using any well-established re-education system.

This same routine is brilliantly successful in the prophylaxis of stammering. To this end, it should be carried out in the case of prodromal stammerers, which procedure would result in the abortment of the defect among school children.

195 BROADWAY.

A PRELIMINARY REPORT OF THE USE OF OZONIZED CHLORINATED OIL OF EUCALYPTUS.*

By J. THOMPSON SCHELL, M.D.,

PHILADELPHIA, PA.

CHIEF SURGEON TO THE NORTHWESTERN GENERAL HOSPITAL.

MANY so-called antiseptics have come before the professions for which extravagant claims have been made by their overenthusiastic advocates, only to fail, or at least to fall far short of what we were led to expect of them.

The search for a perfect germicide began when Lister first applied the principle of Pasteur to the practice of surgery, and this search is still going on. Much has been written about the Dakin-Carrel, Dehelly and Depage solutions, and many remarkable results have been reported from such reliable sources that we are forced to realize that in this solution we have at last an antiseptic or germicide of real value. That the virtue in this solution is dependent entirely upon the amount of available chlorine that is present requires no argument. The perfect germicide must meet two simple requirements: (1) It must kill all parasitic life; (2) it must not harm the cells of the living body.

Quoting from an article by Dakin, Lee, Sweet, Hendrix, and LaConte: "The lethal effects of all the usual germicides on the animal cells, with the clinical results of the retardation and inhibition of the natural processes of repair have become so well recognized of late years that an attitude of antiseptic nihilism has existed. Surgeons have developed a technique which has depended somewhat on soap, water, and alcohol, but chiefly on the natural bacteria resistance of the patient. The tremendous demands made upon surgery incident to the world war, when the surgeons' daily work is made of treating innumerable open and infected wounds, has again stirred our interest in the question of a reliable and active germicide, and the world owes a debt of gratitude to Dakin and Carrel and their co-workers for the introduction of the new and improved chlorine solution."

It has been long recognized that in chlorine we had a powerful but irritating antiseptic, and even in this modern solution Dakin himself says that "the solution must be made with extreme care, and that it is very unstable." He also warns us that "this chlorine solution irritates the skin if it remains in contact with it for any length of time." A few words as to the technique of Dakin, Carrel, Dehelly, Depage.

*Read before Northern Medical Society, March 8, 1918.

1. A constant protection of the skin exposed to the chlorine solution with vaseline is necessary and most important.

2. With the use of a very weak solution of hypochlorites, below 0.4 per cent. of nascent chlorine, the effects are nil; while above 0.5 per cent. the irritation to the skin becomes serious, so that it can be seen at once that a very small margin for variation can be allowed. A concentration of 0.48 per cent. is what is usually employed. My own experience with the use of this solution has been that it is extremely difficult to get the proper solution, and when one does succeed in getting the solution properly made it is very unstable, and will keep but for a very short time. If made fresh daily by a skilled chemist it undoubtedly will give the excellent results claimed for it, but for the ordinary routine of general hospital work, or for the work of the general practitioner, it is not available or practicable. Recognition of this fact has stimulated other workers to produce a substitute for the Dakin-Carrel solution, and they have offered in its stead Dichloramine T.

Let me again quote from Dakin, Lee, Sweet, Hendrix, and LaConte: "It appears that when hypochlorites react with proteins of any kind, one of the first reactions consists in the formation of a substance containing the NaCl group. These products, which belong to the group of the chloramines, are active germicidal agents. Dichloramine T is a synthetic substance made by several methods, as described by Kable, Keiser, Brady, and Chattaway, but is open to almost as many objections as is the Dakin solution, for while it is less irritating, and more simple to apply, it has three great drawbacks. Its three great enemies are light, heat, and water. In addition to this, the solution is not permanent, and cannot be brought in contact with any metallic substance. All these are very serious obstacles to its practical use. Realizing that in chlorine in proper strength and in proper vehicle we had a powerful and valuable germicide, I suggested to C. A. Weeks, a member of the Institute of Chemical Engineers, and a scientific chemist, that he attempt to produce a substance that would be more practicable and more easily handled than the two I have just briefly described. I wish to-night to present to you the new antiseptic, which we have named "dichloride of eucalyptus." This substance is produced by Weeks' formula, as follows: Eucalyptus (not eucalyptol) is first oxidized by means of ozone to destroy the impurities and to make it more readily chlorinated; the resultant product is slightly acid in reaction. This ozonized chlorinated oil is readily miscible in water, and makes a solution that contains 0.02 per cent. of chlorine of sufficient bacterial strength for irrigation; this strength has proved to be very successful clinically, and is stable, not being affected by light, heat, or cold. The solution remained unchanged at the end of thirty days after exposure to the air in an open vessel. This ozonized chlorinated oil is made by direct application of ozone and chlorine to the oil of eucalyptus. The chlorine is obtained from chloride of sodium by electrolysis, and is allowed to pass into the oil until a 20 or even 30 per cent. solution of chlorine is obtained.

Eucalyptus oil contains principally three terpenes: Pinene, COH_2 ; cymene, COH_2 ; cineol or eucalyptol,

COH.; the latter being present in large amounts. The hydrogen in the oil combines with the first chlorine to form hydrochloric acid, which passes off as a gaseous vapor, further chlorination replacing the hydrogen to form a chlorinated product. Upon this replacement of the H by chlorine the stability of the product is established. This product is dichloride of eucalyptus, and contains 30 per cent. of available chlorine; it is a permanent product, non-irritating, and can be used with paraffin oil or petrolatum to any desired strength, and is soluble, or at least miscible with water.

The clinical use of dichloride of eucalyptus, or, for convenience, D. E., has up to this time been very encouraging, and while I do not consider this paper any more than a brief preliminary report, since I have not yet had enough experience to justify me in making any definite claims, still I have been much encouraged by the results noted. Dichloride of eucalyptus can be used either in solution in water, for irrigation, or in an ointment for local application to superficial wounds and ulcers, and I have also used it in this way in certain skin infections, such as acne, with marked results. I have used it locally, combined with equal parts of paraffin oil, painting it on the surface, with no evidence of any irritation following. I have also used it in full strength as a substitute for rubber gloves, and in this particular I hope to prove by a more ripe experience that we have something far superior to rubber gloves, with their many inconveniences and annoyances. By using dichloride of eucalyptus applied to the hands the surgeon has an impervious, non-irritating antiseptic covering that not only protects the patient from infection but also protects the surgeon from an infection from the patient, a matter of no small importance.

A dram to the gallon of lukewarm water makes a solution of sufficient strength for all practical purposes; this has been used to irrigate all kinds of open and infected wounds. After irrigating thoroughly the wound is packed lightly with sterile gauze wet with same solution; this gauze is left in from 12 to 24 hours, occasionally dampening with the solution; then at the end of from 12 to 24 hours, depending on the amount of infection, the gauze is removed, the wound irrigated, and fresh gauze applied. The solution has been used for vaginal irrigation following various plastic operations, with excellent results. Ordinary tap water is all that is required in making the solution either for vaginal irrigation or for treating wounds. I have treated a number of old leg ulcers by first washing with the solution and then applying an ointment of $\frac{1}{2}$ to 1 dram of dichloride of eucalyptus to 1 oz. of vaseline, with rapid healing; always, however, using an elastic bandage to support the venous circulation.

I should like to mention, in passing, that I had under my care a patient upon whom I had performed a radical operation for carcinoma of the breast, requiring the removal of a large area of skin; this wound was skin grafted with only partial success, leaving an area filled with heaped-up granulations about the size of a silver dollar. I treated this wound by means of salt solution, with a slow healing, and I was repeatedly compelled to cut away the exuberant granulations. I finally applied the ointment of dichloride of eucalyptus, $\frac{1}{2}$ dram

to the ounce, and had a rapid healing, with disappearance of the granulations. Up to this time I have used the remedy in solution, ointment, or mixed with paraffin oil 50 per cent., in a fairly large series of cases, and only once have I seen any irritation follow. This patient had a periosteal sarcoma, which was removed and treated with massive doses of x-ray and Coley's fluid, and how much of the irritation was due to the dichloride of eucalyptus and how much to the x-ray I am unable to decide.

A number of wounds have been treated and rendered sterile, and then sutured with good results. Several breast abscesses have been treated with much more rapid healing than is obtained under the usual technique. An axillary abscess, post-typhoidal, reaching from the top of the axilla to the brim of the pelvis, was opened, drained, and irrigated, with complete healing in 15 days. After the wounds are rendered clean, or nearly sterile, the moist packing is abandoned and plain sterile or iodoform gauze is used. The degree of sterility is determined by taking a smear and making a bacterial count. This procedure, however, is used only when suturing of the wound is to be considered.

As I stated in the beginning of this paper, this is only a preliminary report of my experience with dichloride of eucalyptus, and I wish, if possible, to avoid overenthusiasm, to which every one is prone while working out any new procedure. I have invited a number of medical associates to try out this preparation, and their reports seem to more than corroborate my own findings, and I shall be glad to have the cooperation of any one present who wishes to try out this preparation in his own work. According to the experience at the Lankenau Hospital with the Dakin solution (Bodley, Means, and Knox, MEDICAL RECORD, February 23, 1918), it has not been found efficacious in wounds infected with *Bacillus pyocyaneus*, and bichloride solutions were resorted to in that class of infections. To me this seems to point to the weakness of the chlorine content in the Dakin solution, for I have noticed in my own cases, when green pus was present, we got no results with the weak, watery solution; but with the stronger solution, made up with paraffin oil, prompt disappearance of the green pus was noted.

In comparing the dichloride of eucalyptus solution with dichloramine T, it is to be noted that the dichloramine T has an injurious action upon all metallic substances, and therefore no atomizer with metallic parts can be used; this objection does not apply to the eucalyptus solution. For the last few months I have used the dichloride of eucalyptus routinely in my hospital work for disinfecting instruments in dressing trays, instead of alcohol, which we formerly used. In the dispensary service, open and infected wounds are washed with dichloride of eucalyptus solution and then painted with a 50 per cent. solution in paraffin oil; a sterile dressing is then applied, and the results have been very satisfactory. All our infected granulating wounds following burns, and crushed wounds, are treated with the ointment, with very rapid and satisfactory results, for this ointment seems not only to act as an antiseptic but to stimulate the healing process.

In conclusion, I wish to state that as far as my clinical experience with dichloride of eucalyptus has gone I believe that we have in this agent a practical, easily handled, non-irritating but powerful antiseptic, and one that any physician, with a little experience, can learn to use successfully in any of the infected wounds that come to him for treatment. I have not gone into the question of the technique of the surgical treatment of wounds, as it is understood that proper drainage, proper cleansing, and removal of all dead tissue must, of necessity, be attended to in the usual way, as no antiseptic can or should be expected to do the work of the surgeon. Taking it for granted, then, that the proper surgical treatment of the infected wound is carried out, I feel confident that with dichloride of eucalyptus as rapid sterilization of the wound can be produced as by either Dakin solution or dichloramine T, without cumbersome apparatus, or danger of irritation, and by an agent that is simple to handle, and one that can be used in any required and dependable strengths.

1318 LOCUST STREET.

INDIGOCARMINE USED INTRAVENOUSLY FOR LOCATING URETERAL ORIFICES IN TUBERCULOUS CYSTITIS.

By SERGEANT PRICE MARTIN, M.D.,

BUFFALO, N. Y.

TUBERCULOSIS of the urinary bladder is caused by infection of the walls of the bladder with the tubercle bacillus, which may reach that structure by several different paths: First, along the walls of the ureter, secondary to a renal tuberculosis; second, along the walls of the vas deferens, secondary to a tuberculous epididymitis; and third, direct from the blood stream, primary.

Primary tuberculosis of the bladder is very rare. The usual course of the infection in the genitourinary tract is for the tubercle bacilli to be deposited first in the epididymis or the kidney, and then spread down the walls of the vas deferens or the ureter until they reach the wall of the bladder just above and to the outer side of the ureteral opening. At this spot a submucous deposit of miliary tubercles is formed, which later may break down and form a tuberculous ulcer.

In the earliest stage of the disease the cystoscope may reveal the deposit around the mouth of either ureter, though usually only around the diseased one, if the case is secondary to renal infection. The deposit may be to the outer side of one ureteral opening. This suggests that it is secondary to testicular infection. The deposit appears at first as a raised, red, submucous patch, covered with tiny shreds of adherent white debris. As the infection progresses, however, this patch increases in size and gray pin-point areas may become visible. Later still these gray points coalesce and give place to large yellowish areas of irregular size and shape, and eventually these in their turn break down and form definite ulcers. Neighboring ulcers tend to coalesce and form large irregular areas denuded of epithelium. Their floors are irregular, and covered with crusts and sloughs or with projecting exuberant masses of villous granulation tissue, which flutters about in

the urine, and which may even be mistaken for carcinoma or papilloma. Their edges are rounded or irregular and undermined and surrounded by swollen reddened mucous membrane which has a tendency to bleed easily when touched, and which may exhibit gray or yellow tubercles.

The above changes microscopically appear as follows: Tubercle bacilli are deposited first in the submucous tissue spaces and produce hyperemia, exudation and proliferation of round and spindle cells with the formation of miliary tubercles. These coalesce, undergo necrosis, and give rise to submucous collections of yellow, cheesy material. The epithelium on top of this area then undergoes necrosis and disappears, leaving the cheesy material to be discharged into the bladder so that an ulcer is formed, the floor and edges of which are lined with tuberculous granulation tissue.

The process may spread through the muscle coat to the perimuscular connective tissues producing necrosis and abscesses in these tissues. Great care should be taken while inserting a cystoscope in advanced cases not to pass the instrument completely through the friable bladder wall.

In chronic cases there is usually a progressive inflammation with resulting sclerosis of the fibrolipomatous perivesical tissue continuous with that surrounding the infected ureter and kidney. The walls of the bladder are thus thickened, and by reason of muscular hypertrophy from frequent urination and from a progressive sclerosis the cavity of the bladder is greatly diminished in size. In many cases it may hold no more than an ounce of urine.

The disease may begin suddenly with frequency in urination and burning pain during micturition, or it may be so gradual in onset that the patient is unable to recall when the trouble first began. The pain as a rule is not severe and is characterized more by a burning sensation felt along the deep urethra and in the glans penis. At first urination may occur every one to two hours, both day and night. This gradually increases, however, till in the later stage of the disease urine may be voided as often as every ten or fifteen minutes. As a rule a greatly increased quantity of urine is passed in twenty-four hours, which may be due to reflex kidney irritation.

In the early stages of the disease there is, as a rule, no general symptoms such as pyrexia, weight loss, or anemia, and the patient may appear healthy and well. Later, however, after the onset of secondary infection or of very extensive ulceration of the whole urinary tract, cachexia and hectic temperature may be present. In these later stages the suffering is constant from the frequent agonizing calls of the bladder to empty itself. This may also be a factor in the rapid loss of weight.

In the early stage the urine may appear clear to the naked eye, or contain little white flaky shreds floating on the surface, which are very suggestive if there has been no previous history of gonorrheal urethritis, though examination generally will reveal a trace of albumin, a few red blood cells in centrifuged specimen, and even tubercle bacilli. Hematuria is not common at the onset; though a few drops of blood may be passed

at the end of micturition for the first few days and occasionally the disease even may be ushered in by a profuse hematuria lasting several days. Hematuria is seldom repeated, save in the later stages when there is extensive ulceration.

Pyuria for a long time may be intermittent, exacerbations of the discharge being marked by the formation of fresh ulcers. In the later stages it may be constant.

In cases of tuberculosis of the bladder secondary to a renal tuberculosis the chief symptoms are those of an irritable bladder which may be accompanied by a constant dull, aching pain, or intermittent attacks of dull pain in the loin on the infected side. Hematuria may or may not be present, but pyuria is usually well established, especially in the well-advanced stages. In cases secondary to tuberculous epididymis the first symptom may start with a sudden profuse hematuria, followed by the aforesaid symptoms of irritable bladder. A firm, irregular nodule felt in the epididymis will also prove a great aid in the diagnosis.

The finding of the tubercle bacillus in the urine accompanied by pyuria or other local symptoms and signs will tend to confirm the diagnosis of tuberculous cystitis. The specimen of urine, however, must be obtained free from the smegma bacillus, because, as yet the bacteriologist is not prepared to distinguish between these two acid-fast bacilli by staining methods alone. The smegma bacillus may be excluded by cleansing the glans penis or vulva for several minutes with swabs and hot soap and water. In a male the penile and bulbous urethra should then be flushed out thoroughly by means of a urethral nozzle, using sterile warm water. The patient can then void part of his urine to flush out further the urethra while the remainder of the urine is passed direct into a sterile flask, or a sterile catheter may be introduced into the bladder and all the urine withdrawn into a similar flask. Examination is then made of stained films of the centrifuged urine. In any doubtful cases, however, the diagnosis based upon finding acid-fast bacilli should be further confirmed for tuberculosis by guinea-pig inoculation.

It used to be held that cystoscopy was seldom required in the male in cases of tuberculosis of the bladder; the risks of setting up secondary infection were considered to be so great that at any cost cystoscopy was avoided. Owing to a change in modern conception of the origin of tuberculosis of the bladder, however, it is now held that the patient's best chance of cure depends on early cystoscopy. Primary tuberculosis of the bladder is a very uncommon event and many leading urologists are of the opinion that such a condition never really exists; the disease being secondary to tuberculosis in the kidney or epididymis, or both.

If the infected kidney or testicle and vas can be removed in the early stages the bladder appears to be able ultimately to overcome the infection, if reinfections are prevented.

Without cystoscopy it is impossible to ascertain accurately whether one or both kidneys are infected, or what the functional power of each is.

It is therefore important to be able to locate the ureteral openings.

In diffuse tuberculous cystitis, when the bladder has become greatly reduced in size and the slightest movement of the inserted cystoscope causes the entire cystoscopic field to become bloody, it is by no means an easy matter to locate either ureteral opening even though one kidney is normal. It is in this type of cases that the employment of indigocarmine intravenously may prove of great value by causing a blue spurt of urine to appear from the ureteral orifices against a diffuse red background and thus act as a target at which to direct the ureteral catheter.

Voelkner and Joseph brought forth the use of indigocarmine as a test of renal function in 1903. They used a 4 per cent. solution of the dye, injecting 4 c.c. into the gluteal region. These observers made a careful study of the time of its appearance in the urine, the quality of the color, and the frequency and force of the ejections at the meatus. Indigocarmine has been extensively used in Europe during the past ten years, and to some extent in America as a test of renal function.

Peterson reported in 1915 in the cystoscopic examination of a woman with marked cystitis, that it was impossible to see the ureteral mouths. Ten cubic centimeters of a 1 per cent. solution of indigocarmine was then injected into the gluteal region and ureteral catheterization was accomplished readily after the appearance of the dye.

While an assistant in the Urological Department of the Mayo Clinic I saw and employed this method with very satisfactory results in several cases of severe cystitis. In all these cases it had been impossible to locate the ureteral openings until after the appearance of the dye.

In tuberculous cystitis, when there is difficulty in locating the ureteral orifices, the following procedure is recommended: Inject 2 c.c. of a saturated solution of indigocarmine into one of the veins at the bend of the elbow after the cystoscope has been used for inspection of the bladder, and while it is still in place. The region of the trigone is then kept under observation for the appearance of the blue color. The time of appearance of the dye on each side may be recorded. The catheters are then passed into the ureters and specimens collected for microscopic study. The dye as a rule will appear in the urine in from two to twelve minutes after the injection.

In the following cases of tuberculous cystitis cystoscoped during the past year, I used indigocarmine to locate the ureteral openings:

CASE I.—F. S., male, aged 25. Duration of symptoms, six months. Urinalysis showed acid reaction, specific gravity 1014, moderate amount of albumin, no sugar, pus in abundance, and tubercle bacilli present. Cystoscopic examination performed in November, 1917, revealed a severe diffuse cystitis. I was unable to see either ureteral opening; the bladder capacity was six ounces. Two c.c. of indigocarmine was then injected intravenously. The dye returned from the right ureteral opening in two and one-half minutes. This ureter was then readily catheterized and specimens collected, which contained no pus or tubercle bacilli on examination. There was no return of dye from the left ureteral opening at the end of fifteen minutes. This ureteral opening was not located. A phthalein functional test was then made. The phthalein returned in three minutes from the right kidney and showed up

3 per cent. for the first fifteen minutes and 9 per cent. for the second fifteen minutes. Examination of the catheterized bladder specimen taken at the end of the second fifteen minutes, while the right ureteral catheter was still in the ureter, showed no trace of phthalein. Left nephrectomy performed two weeks later revealed a large tuberculous kidney.

CASE II.—L. K., male, aged 45. Duration of symptoms, one year. Urinalysis showed acid reaction, specific gravity 1020, trace of albumin, no sugar, small amount of pus, and tubercle bacilli present. Cystoscopic examination performed in August, 1917, revealed a diffuse cystitis; bladder capacity six ounces. The left ureteral opening was located with difficulty and clear urine appeared to be spurting from it. This ureter was then catheterized. The right ureteral opening, however, could not be located, until after 2 c.c. of indigocarmine had been injected intravenously. The dye then returned only faintly at the end of ten minutes but was of sufficient strength to locate the ureteral mouth. The right ureter was then catheterized. Specimens were collected from each side which were examined for tubercle bacilli. The specimen from the left kidney proved to be entirely normal, while that from the right kidney contained a moderate amount of pus, and tubercle bacilli were present. A differential phthalein functional test showed a return of the dye from the left kidney in three minutes, and from the right kidney in eleven minutes. The specimen from the left kidney examined for the first fifteen minutes showed 15 per cent. of phthalein present, while that from the right side showed only a trace. There was 17 per cent. of phthalein from the left side at the end of the second fifteen minutes and only 2 per cent. from the right side. The bladder specimen contained 1 per cent. of phthalein at the end of the second fifteen minutes. Right nephrectomy was advised, but the patient refused operation.

CASE III.—Mrs. M. H., female, aged 25. Duration of symptoms, two years. Urinalysis showed acid reaction, specific gravity 1025, much albumin, no sugar, pus in abundance, and tubercle bacilli present. Cystoscopic examination performed in August, 1917, under a general anesthetic revealed a greatly contracted bladder with marked diffuse cystitis. Bladder capacity one and one-half ounces. Neither ureteral opening could be located. Two c.c. of indigocarmine was then injected intravenously. The dye made its appearance faintly from each side at the end of fifteen minutes. A number four ureter catheter was then inserted into each ureter and specimens collected. Examination of the urine thus obtained showed tubercle bacilli and pus present in each kidney. The patient was referred to a tuberculosis sanatorium.

CASE IV.—J. R., male, aged 32. Duration of symptoms, six years. Urinalysis showed acid reaction, specific gravity 1017, moderate amount of albumin, no sugar, pus in abundance, and tubercle bacilli present. Cystoscopic examination performed in February, 1917, revealed a severe diffuse cystitis, the entire cystoscopic field was very bloody and neither ureteral opening could be located. The bladder capacity was four ounces. Two c.c. of indigocarmine was then injected intravenously. The dye returned from the right ureteral opening in five minutes. This ureter was then catheterized, and examination of specimens collected from this side showed no pus or tubercle bacilli present. There was no return of dye from the left ureteral opening. The phthalein functional test showed a return of the phthalein in five minutes from the right kidney, and the specimen collected for the first fifteen minutes from this side contained 20 per cent. of the dye. The specimen collected for the second fifteen minutes also contained 20 per cent. of phthalein. The catheterized bladder specimen taken at the end of the second fifteen minutes revealed no trace of the phthalein. Left nephrectomy performed three days later revealed a tuberculous pyonephrosis.

In review of the literature Peterson gives the most complete description of the physical and chemical properties of indigocarmine. He states that indigocarmine is the sodium or potassium salt of indigo disulphonic acid ($\text{H}_2\text{C}_8\text{H}_6\text{N}_2\text{O}_6$).

(SO_3)₂. It is soluble in water; 0.8 per cent., and is of a dark blue color. Its reaction to litmus is neutral and can be sterilized by boiling or by steam pressure.

By addition of sodium hydrate solution the blue is changed to a yellow color and on the addition of sodium hydrate solution and boiling, a clear solution is obtained. If sodium hydrate is added to a solution of indigocarmine until all trace of blue disappears, and a pale yellow color is obtained, on the addition of acetic acid it again becomes the characteristic blue of indigocarmine. By rendering a solution distinctly alkaline and then boiling the solution a complete oxidation occurs and the acetic acid does not restore its color.

The behavior of indigocarmine toward sodium hydrate makes it possible to bring out the characteristic red of phthalein by adding sodium hydrate, which at the same time causes the blue color to disappear. Thus the phthalein functional test may be employed satisfactorily after using indigocarmine to locate the ureteral orifices. Indigocarmine is stable in ordinary watery solution, and in the presence of acetic acid. The dye is rapidly oxidized by nitric acid and less affected by hydrochloric acid. By slowly adding sodium hydrate to a solution of indigocarmine the color first changes to a greenish tinge and finally to a light yellow. Indigocarmine is soluble in water 0.8 per cent. It has been noted that when a stronger suspension of the dye is injected intravenously transitory symptoms of shock varying from mild manifestations, such as dizziness and pallor, to complete collapse will occasionally occur. These manifestations may possibly be due to the action of undissolved particles of the dye as momentary thrombi. For this reason the dye should be used intravenously only when in complete solution and carefully sterilized.

504 ELECTRIC BUILDING.

Syphilis and Maleness of Offspring.—Sex determinants have not been permanently isolated in connection with the human race but according to Girault and Tissier, Maurel was right in his recent claim that syphilis in parents reduces the number of male births. These authors found that 201 syphilitic mothers gave birth to 119 boys and 82 girls; but that of 97 macerated still-born children 60 were males. This was slightly offset by the fact that in 40 deaths soon after birth 24 occurred in girls, but the net result as seen in the living healthy children was 43 boys and 21 girls. In other words, of 124 non-survivors 76 were boys and but 48 were girls, or, in round figures, syphilis killed 3 boys for every 2 girls.—*Le Progrès Médical*.

THE TREATMENT OF FLAT FEET.

BY LEO MAYER, A.M., M.D.,

NEW YORK.

WHOEVER has read Dr. Whitman's original publication on the subject of flat feet (Transactions of the American Orthopedic Association, 1889) must be impressed by the lucidity of explanation and the cogency of the author's argument. That the writer knew his own mind clearly, is well evidenced by the fact that since the time this article appeared he has altered his opinions in scarcely a single detail. Little wonder that his teaching should gradually have become the dominant one in this country and that the Whitman foot-plate should be recognized as the standard.

Yet, despite the gratitude which all medical men owe Dr. Whitman for the light he has thrown upon the etiology and treatment of this lesion, I venture to offer the heterodox opinion that, theoretically, his original communication is not entirely sound, and that practically the orthopedist will be confronted by a number of cases which do not yield readily to his method of treatment. The theoretical weakness of Whitman's arguments lies not in his conception of the etiology, but in the application of the anatomical facts to the therapy. It is true that the flat foot represents a subluxation, but it does not follow that the only proper method of treatment is the reduction of this subluxation at each step by means of a powerful lever. This method may work very well in instances where the patient is able to stand the pain of this oft-repeated act of reduction, but in many instances the flesh will rebel against such a procedure. Whitman states (page 130) that the brace should be light, inelastic, and comfortable. My experience has shown me that for many patients it is uncomfortable to such a degree as to prevent them from wearing it; secondly, that they frequently complain of its excessive weight; and, thirdly, that the demand for inelasticity fails to recognize the normal spring of the arch which Virchow and Fick have demonstrated.

During the past three years I have been trying a plate which seems to me to meet the physiological requirements and is both light and comfortable. With practically no exceptions it has entirely relieved the symptoms of the 500 patients treated, and when combined with exercises it has frequently completely cured the deformity.

The technique of making it is simple, but not a little experience is necessary before those minute modifications can be properly appreciated, which mean the success or failure of its application. A plaster model of the feet is not necessary. Simply an impression is taken as shown in the accompanying illustration. With this as a guide, a paper pattern is cut out. On the inner side this reaches forward to a point just back of the bearing area of the first metatarsal bone; on the outer side to a point just back of the head of the fifth metatarsal bone. Its width anteriorly should be somewhat less than that of the foot. At the heel it reaches slightly beyond the impression on all sides. On the inner side the line joining the heel with the anterior tip must be so made as to allow for raising the arch. It is therefore convex with the most prominent point corresponding to the position of the scaphoid. Anteriorly there should be a concavity (C), since

otherwise the plate would cut the leather of the shoe. From this paper form a celluloid model is cut out. This is readily done with an ordinary saw and filed down until it corresponds exactly with the paper outline. To shape the celluloid plate, it is kept in boiling water until sufficiently softened to permit accurate molding. It is this step of the technique which requires practice, since in each individual instance the molding differs according to the type of deformity present. If the deformity is chiefly one of planus with a little tendency to valgus, the support is made with comparatively little difference in the height of the outer and the inner margins. If, however, there is no planus but marked valgus, then the plate must be so molded as to tip the foot by raising the inner border and depressing the outer border. If there is a depression of the anterior arch, the anterior portion of the plate must be bowed so as to support the metatarsal bones. These are merely a few indications of the numerous possible modifications.

One feature is particularly important, namely, to

Impression of a child's foot showing planus deformity and the outline of the author's flat-foot brace. Note that the inner margin has a double curve—convex near the center so as to allow for raising the arch, concave anteriorly (C), since otherwise the plate would tend to cut the shoe. The "I" indicates the bearing surface of the first metatarsal bone; the "V" the head of the fifth metatarsal bone.

make the transverse curve of the support correspond with the anatomical curve. Almost every other arch support which I have seen is concave from side to side. This is anatomically incorrect, since the tarsal bones, as well as the metatarsals, are held together in such a way as to form an arch, whose convexity points upward—not downward. The plate must have a corresponding cross section, *i. e.* it must not be concave, but convex.

The celluloid plate, when molded, is rapidly cooled in running water and can at once be tried on the patient. Frequently it is possible to decide at once that it is correct. In other instances it is advisable to allow the patient two or three days to try out the model before a leather-covered metal plate, corresponding accurately in form to the celluloid, is made as the permanent brace. This gives slightly with each step. It is gratifying to note the quick alleviation of pain and the readiness with which the patient accustoms himself to the new support.

The brace constitutes, of course, only one phase of the treatment, whose other factors—exercise, correct foot hygiene, and, in certain instances a night splint—are equally important in the successful management of the case.

41 WEST EIGHTY-THIRD STREET.

Medicolegal Notes.

Liability of a Charitable Hospital for Negligence of Its Agents.—On the ground of diversity of citizenship, an action was begun in the federal court against a hospital, chartered under the laws of the State of Pennsylvania as a charitable corporation, to recover on account of the death of a patient. The Circuit Court of Appeals, Third Circuit, holds that the federal court should, on the ground of comity if for no other reason, follow the States rules as to the liability of such hospitals. The court found that the inapplicability of the doctrine of respondeat superior to charitable corporations has crystallized in Pennsylvania into a rule of property. It said: "We have examined the whole range of learned and lengthy opinions cited on this general subject, but we refrain from entering the tempting field of joining in such discussion. Whatever may be the grounds for their conclusions, the Pennsylvania decisions and those in accord therewith have adjudged two things, namely, that hospitals and the like are public charities; and, secondly, that the law does not impose liability on such charities for negligence of an agent in administering such charity to beneficiaries. Some decisions are based on restricting trust funds to fulfill trust purposes, some on the public character of the trust, and some treat the exemption as an exception from a general liability. We see nothing to be gained by an abstract discussion of these theories. The simple fact is that if liability by a hospital, to a patient, for the negligence of a nurse exists, it is one imposed by law and is not created by contract. The imposition of that liability, in other words, invoking the legal principle of respondeat superior, was, when the question originally arose in Pennsylvania, largely a question of judicial discretion, and the due exercise of that discretion involved, on the one hand, the broad field of invoking, encouraging, safeguarding, and perpetuating charitable gifts and trusts, and, on the other, a due regard for the welfare and protection of those who availed themselves of the ministrations of these charities. With this in view, the Pennsylvania courts charged with the responsibility of imposing or not imposing liability, and leaving the wide field of encouraging, as well as of beneficially administering, charitable trusts, held they could not impose liability on the part of the trust to a beneficiary for the negligent act of an employee or agent in administering its benefits. Whatever the reasoning process by which it is reached, the conclusion commends itself to us.

"The many accidents resulting from the industrial pre-eminence of Pennsylvania have called into being hospitals in every section of the State. These hospitals have in turn inspired large private and State benefactions, and have called to their directorship the most efficient, careful and thoughtful of men and women. The outcome has been that for one patient injured by a nurse's negligence, thousands have had a degree of solicitous care far in excess of a legal standard of mere duty. The unselfish aims of charities, the high grade of thoughtfully careful people whom the very nature of such charities enlist in their service, the voluntary act of recipients in seeking their aid, the comparatively few cases in which nurses have proved negligent, all unite to vindicate the far-seeing wisdom of the earlier decisions of Pennsylvania which refuse to impose liability on a hospital for the negligence of a nurse, and we see no reason why this court should depart from, and every reason why it should abide by, this ruling of the Pennsylvania courts."—Judgment for the hospital was affirmed.—*Paterlini v. Memorial Hospital Assn. of Monongahela City, Pa.*, 247 Fed. 639.

Malpractice—Insufficient Evidence—Expert Opinion.—Action was brought for the death of the plaintiff's wife, which was alleged to have been caused by the defendant's negligence, unskillfulness and carelessness

while performing an operation upon her for chronic ovaritis. From the testimony it appeared that the patient had long been a sufferer, and perhaps because of her almost constant pain she had become addicted to the use of morphine, and in addition had contracted other ailments more or less dangerous, and at the time of the operation complained of she was in an exceedingly precarious condition. The operation occurred in November, 1916, and in the early part of that year two minor operations had been performed by the defendant; but the one in November, the major operation, was that about which negligence was charged. Other physicians and a trained nurse attended the operation, and the latter gave to and received from the defendant the gauze pads which he used. The patient showed signs of dissolution, and the cavity was hurriedly closed up to prevent it, and shortly thereafter the nurse discovered that one of the pads was missing. In closing up the cavity, as is usual in such cases, a gauze drainage was arranged so as to let out pus or other deleterious substances, and in it was one of the pads, which was discovered four days after the operation by the wound being opened up, at which time some of the parts, including some of the smaller intestines, were found to be inflamed, and the patient shortly died. The chief act of negligence complained of was that of leaving the pad in the wound, but under the evidence and instructions of the court the jury found that this was not an act of negligence, or, if it was, it could not be termed the proximate cause of the patient's death, and accordingly returned a verdict for the defendant.

On appeal, the Kentucky Court of Appeals hold that, though an act may be negligent, and involve a violation of duty, before a cause of action can be predicated thereon the injury flowing therefrom must have been the proximate result of such dereliction. It also holds that medical witnesses were properly allowed to state in substance that an operation was practiced according to the approved methods of the medical profession, and that the patient in her diseased and run-down condition would have died and as a matter of fact did die from such conditions, though the defendant left a pad in the wound, since, though an expert witness may not take the place of the jury by stating whether certain acts constituted negligence, he may give his opinion in regard to matters which require scientific or specialized knowledge or experience, and for which the general common sense and practical experience of the jury are inadequate. The court added that this rule should not be extended to permit witnesses to testify to conclusions on matters within the common scope of knowledge and experience. Evidence given by some of the physicians who assisted at the operation concerning statements made by the defendant relating to the conditions which he found in the patient, and other subjects connected with the operation, during and while he was performing it, was held admissible as part of the *res gestae*.

After defining the defendant's duty on undertaking the operation, the court properly instructed as to liability, "and they (the jury) further believe from the evidence that such negligence or want of care, if any, on the part of defendant, was the proximate cause of the death of decedent," without adding that the decedent's death "was not caused by ovaritis or other disease, if any, not produced by the operation." It was not necessary for the court in its instructions to define what constituted an operation, since any ordinary layman would know that an "operation" included everything done, from its commencement until it was completely finished. The evidence was held to sustain the verdict for the defendant, the patient's condition having been so precarious that it could not be said that any negligence was the proximate cause of the death.—*Barrett's Adm'r. v. Brand (Ky.)*, 201 S.W. 331.

Promise to Pay for Services to Another.—The Texas Court of Civil Appeals holds, in an action for payment for professional services, that where the defendant injured a boy, and took him to the plaintiff's hospital, and requested the plaintiff to treat the boy's broken leg, the defendant's agreement to pay the plaintiff for his services was an original undertaking of the defendant's, not within the statute of frauds as to a promise to pay for the debt, default, or miscarriage of another.—*Banfield v. Davidson (Tex.)*, 201 S.W. 442.

Military Medicine.

PATHOLOGICAL ANATOMY OF SECONDARY HEMORRHAGE AFTER WAR WOUNDS.

SECONDARY hemorrhage as met with in the surgery of warfare is of two kinds. The first, which is unquestionably the most frequent, is produced by lesions of important vessels; the second type being general oozing from badly drained cavities which are lined with granulation tissue bathed in pus. Hemorrhages resulting from vascular ulcerative processes are the freest, therefore the most serious. Occasionally the vessel is simply fissured, but generally the loss of blood is the result of a tear or an ulceration of the vessel walls. In a septic or gangrenous wound, the terminal portion of the vessels, having undergone inflammatory changes, rupture upon the slightest contact. Usually, however, the hemorrhage comes from an ulceration of one of the large trunks, such as the femoral, axillary, or external iliac arteries, or popliteal veins. Cases have been met with in which, after the most minute inspection, no lesion could be detected, the hemorrhage resulting from general oozing.

Secondary hemorrhage occurs in the major traumata with serious infection, such as diffuse phlegmon, gas gangrene, and compound fractures. In phlegmonous processes the arteries, surrounded by pus, are dissected out of the tissues and, as they do not resist the microbic invasion, ulceration of their walls occurs. Consequently, all necessary conditions for the production of serious hemorrhage arise. In compound fractures with the almost inevitable infection of the battlefield, the bone splinters and fragments contaminate the arteries and favor the development of a septic process in their walls, while their mechanical action greatly aids the nefarious work of the bacteria present in the traumatic focus. The ultimate outcome of all this is a secondary hemorrhage from some large vascular trunk, such as the axillary or humeral, for example, necessitating ligation of these vessels, with all the danger that is inherent in such an interference, even when carried on under the most favorable circumstances.

Such are the arterial changes in traumatism of warfare. Their pathogenesis can be briefly summed up as follows: The suppurative process invades the periarterial connective tissue, provoking a progressive disaggregation therein, finally to end in denudation of the vessel. The mesarterium, in contact with the suppurating mass from this time on, directly impregnated with the bacterial toxins, degenerates and loses all resistance. The endarterium, involved in its turn by the toxins which become diffused through the partially necrosed middle layer, reacts by a hypertrophic process. At this time the walls of the vessels, in contact with the pus, are composed of (1) a very thickened, fibrous endarterium, (2) a degenerated, necrosed mesarterium whose external layers are infiltrated with pus and destined to undergo early distention, followed by rupture. By the force of the blood current, the thickened and purely fibrous endarterium becomes distended; the degenerated mesarterium which has attained the limit of its resistance becomes fissured, so that at certain points the en-

arterium is in direct contact with the pus and is infiltrated by it. The dilatation becomes progressively more marked and finally the endarterium suddenly gives way at a point of lesser resistance.

The Returned Soldier in Canada.—The Canadian Parliament some time ago appointed a Special Committee on Returned Soldiers. The report of that committee makes the following recommendations: That both federal and provincial authorities take up without delay effective measures to prevent the spread of tuberculosis; that those soldiers who are hopelessly insane be cared for at the expense of the Federal Government in provincial institutions under the same conditions as fellow citizens similarly affected; that returned soldiers who are suffering from venereal diseases be quarantined at the port of arrival in Canada until cured; that orthopedic institutions be provided at centers throughout Canada, in addition to the one located at Toronto; that a sufficient number of returned men be induced to learn and follow the manufacture of artificial limbs, and that their services be utilized to supply limbs to soldiers free of cost, and renewals and repairs at the cost of the State during the lifetime of the soldiers; that returned men who have been undergoing convalescent treatment and have partly completed courses of vocational training be allowed to continue such courses for a period of two months after their discharge as medically fit, if in the opinion of the vocational training officer of the district, it is in the interest of the State and of themselves that they should do so.

MEDICAL SECTION OF THE COUNCIL OF NATIONAL DEFENSE.

The annual meeting of this body was held in Washington, D. C., May 4 and 5, 1918, under the chairmanship of Dr. Edward Martin of Philadelphia.

Surgeon General GORGAS, U. S. A., in addressing the meeting, alluded to the age of the Medical Reserve Corps of the United States Army which he said was eight or ten years older than any similar organization. At the outbreak of the war its membership was only about fourteen hundred, but was now about twenty-eight or thirty thousand; five thousand more men could be used at the present time and General Pershing had just notified the Surgeon General that he wanted five hundred more doctors at once.

Surgeon General BRAISTED of the United States Navy spoke on the activities of the naval surgeons. The navy medical corps was not as large as that of the army, he said, but the need in that branch of the service was just as real. The work done by the naval surgeons during the past year had been of the very highest character.

Col. BERT CALDWELL, U. S. A., gave some information about the personnel of the Medical Reserve Corps. He stated that of the first 23,059 doctors who had applied for commissions in the Medical Reserve Corps during the past year 1,598 declined the commission and 1,656 had been discharged from active service. There were now in the Reserve Corps 1,252 majors, 4,584 captains, and 12,370 lieutenants. On active duty there were 1,170 majors, 4,158 captains, and 11,224 first lieutenants. In the National Guard there were 19 lieutenant-colonels, 246 majors, 150 captains, and 790 lieutenants. In the Medical Corps of the regular army there were 3 brigadier-generals, 12 colonels, 91 lieutenant-colonels, and 8 majors. In the United States there were approximately 150,000 doctors; of these one out of every twelve had joined the army. There were about 76,000 between the ages of twenty-two and forty-five, and one out of every eight of these had joined. Colonel Caldwell believed

that it would never be necessary to draft physicians. The Surgeon General wanted to mobilize the profession and all who were qualified should join the Reserve Corps; then the Surgeon General could supply the army with competent officers and the whole thing would be easy. It was useless to apply for a commission in the Medical Reserve Corps if one was over fifty-five years old or was unfit for active duty. In the latter case very restricted duty could be given, but this was a matter which would be decided individually.

Surgeon JOSEPH A. MURPHY of the United States Navy said that one thousand men would be needed in the navy during the coming year, or an average of one hundred a month. So far fifty a month had been the average. The needs of the navy were always exceeding the estimates. For example, when the Dutch vessels were taken over lately there was a call for medical officers for them. The age limit of naval officers was forty-four years, because they were more likely to be subjected to hardships than men in the army. They were sometimes stationed in some small place where they were obliged to do all kinds of work. In France the naval surgeons were expected to treat the civil population. Many retired officers had been called back into active service only to break down. Later on older men would be called upon for service in this country to replace the younger men who had been called abroad. The doctor entering the navy, whether he was an internist, surgeon, or a specialist, might be required at first to vaccinate, examine troops, etc. He might have to do military duty, serve on courts martial, on various boards, do inspection work, etc.; he might be required to do bacteriology and even gynecology. Hence the all-around man was more useful than the specialist, although the latter could be used in base hospitals, two of which had been established abroad of five hundred beds each. There was a bill before Congress which would almost double the navy.

Dr. J. D. MCLEAN reviewed some of the activities of the States' Committees. They had been making a list of the doctors available for the Medical Reserve Corps and those not available. They had corresponded with the State Committees in regard to the exemption of internes, etc. They had obtained official rulings from the Surgeon General's office and transmitted them to the States. They had helped to combat venereal diseases and were daily answering many letters of inquiry.

Dr. E. P. DAVIS told of the activities of the Volunteer Medical Service Corps. Some doctors were ineligible for the Medical Reserve Corps, yet wished to serve their country. Some of these taught in medical schools, held State hospital jobs, or helped in sanitation work. Others wished to serve in other ways, and the outcome had been the organization of this body. The five thousand doctors who had applied for commissions in the Medical Reserve Corps and been rejected would be given membership first. All services were voluntary and might consist of such things as going as consultants to neighboring camps, and the like. The membership was made up of doctors who would be taken in the Medical Reserve Corps except for disqualification on account of age or sex.

Dr. FRANKLIN MARTIN told of the great need of the allied armies, which need doctors more than fighting men; England and France needed two thousand doctors at once. At the front they were working in two twelve-hour shifts. The wounded and sick extended for half a mile around the hospitals, and orderlies were sent out to get the worst cases.

A letter from President Wilson was read expressing his appreciation of the efforts of the Medical Section.

Senator OWEN addressed the meeting at the afternoon session and spoke of the great need of higher rank for medical officers. Other countries, he said, found it necessary, and in France, England, and Japan there were twice as many general medical officers in proportion as there were in the United States. Higher rank should be given military surgeons, to enable them to do their work more effectively and not as a reward. No rank, he said, which the United States could give, could add more dignity to a Crile or a Mayo. The medical corps of the army needed 20,000 officers, 50,000 nurses, 200,000 hospital corps men, and 500,000 beds at once.

Senator HOWARD SUTHERLAND of West Virginia addressed the meeting on May 5, and after speaking of

the sacrifices which had been made by American physicians in giving up lucrative practices to go to war, he said that he had been greatly impressed by the claims made by the American medical profession for increased recognition. He believed that the feeling of the committee on military affairs in the United States Senate was favorable and he for one pledged his aid to secure higher rank. The bill might not be available in its present form, but undoubtedly one would be drafted which would be satisfactory to the profession; in fact, a sub-committee had already been appointed to do this.

Surgeon-General GORGAS expressed appreciation of Senator Sutherland's remarks. He wished to call the Senator's attention to the fact that the Medical Reserve Corps comprised 90 per cent. of the personnel of military surgeons. If the present bill was passed it would mean the addition of five general officers, 40 colonels, and 80 lieutenant-colonels.

Dr. FRANKLIN MARTIN reviewed the past year's work of the Advisory Board and enumerated the various conferences which had been held and the committees which had been appointed. Many of the latter, he said, had been taken over by the Surgeon-General's office which was indicative of the important work the board had been doing.

Dr. E. P. DAVIS said that applications were coming in fast for the Volunteer Medical Service Corps. Invitations were first sent out to the 5,000 physicians who had tried ineffectually to get into the Medical Reserve Corps. Next, to all members of Medical Advisory Boards who were over 55 years of age and finally to members of leading medical societies who were over fifty-five. Other applications would be sent out to properly qualified persons in due time. The Secretary of War had given his approval of this body as well as of its insignia. Qualifications for entrance were very high.

Major BASCOM JOHNSON reported for the Committee on Training Camp Activities. He stated that lawyers as well as doctors had been found necessary in carrying out this work as it was found necessary in dealing with civil authorities to use persuasion and even coercion before proper co-operation was obtained. Special attention had to be given to the venereal disease problem. In doing this it was found that communities were usually to blame and not military activities. It had given a great deal of time to providing wholesome recreation for the men and to cleaning up "venereal swamps." "Red-light districts" had been eliminated for five miles around every military and navy camp. Seventy-five of these districts had been abolished in the past nine months. In dealing with the alcohol problem, Texas offered considerable difficulty as it was a "wet" State and there were 300,000 troops there. The Governor was asked for legislation and several weeks ago dry zones of ten miles in extent were established around every army and navy station and ship-building plant.

Major WILLIAM F. SNOW reviewed the history of the fight against venereal disease. It was early found necessary to enlist the aid of the public. This had been secured to a gratifying extent. United States legislation had been applied for and obtained and perhaps by next year this disease would be placed on a proper epidemiological basis. Dr. Snow then exhibited charts showing the decrease in the prevalence of venereal disease in the army and the results of prophylactic treatment. He suggested that drafted men should be protected from the time they leave home as many infections occur *en route* to the training camp. Workers in United States industries should also be protected.

Assistant-Surgeon JOSEPH A. MURPHY reviewed the activities of the medical department of the Navy during the past year. The health of the Navy had been quite as good as in times of peace in spite of the rapid extension of the service and the breaking in of new men. Hospitals had been built, increasing the capacity from 3,800 to more than 15,000. The Navy nursing corps had been increased to over 900 women. Hospital corps men had been increased from 1,500 to nearly 9,000, and schools had been built to train them. Three base hospitals had been established abroad for the Navy sick and two more were ready to go. By next fall the Navy expected to have available 25,000 beds.

Mr. HOMER SMITH presented the report of the Committee on Supplies. He said there had been a gratifying response from manufacturers of medicine all over the country to the Government's appeal for aid in relieving the stringency of the war situation. As a result the supply of many necessary drugs had become adequate.

Colonel NOBLE presented the report of the Committee on Hospitals. He stated that the situation was much better than believed. When the war started there were four general hospitals which with the post hospitals had 4,000 beds. Fifty-eight hospitals had been added. By July it was expected that 90,000 beds would be available. In the United States now there were 22,000 empty beds available, this being partly due to the improved situation in venereal disease. Hospitals for overseas were being prepared. There must be hospital accommodations of 4,000 beds for every division. Today we had enough beds in this country not only for our own use but for any sick or wounded who might be returned from abroad.

Dr. OTTO GEIER presented a report of the Committee on Industrial Medicine and Surgery. This committee had to deal with the problem of securing sufficient men for the army for various industries. Physicians were needed to see that workers were kept in good health. The principal causes of slowing up of the production of war materials were excessive turn-over of labor and physical breakdowns. Three times as many industrial workers were maimed in a year as we expected to receive from the United States Army in the same length of time. The present non-effective rate of industrial workers was six per cent., and this could be cut in half by proper attention.

Lieutenant-Colonel WILLIAM H. WELCH of Johns Hopkins presented the report of the Committee on Nursing Conditions. The purpose of this committee was two-fold: To increase the number of student nurses and to assist the Red Cross to secure graduate nurses. There were 83,715 graduate nurses in the United States and of these 66,017 were registered; 14,387 would be graduated at the end of the year, making a total available then of 98,162. There were 42,671 student nurses in the schools and of these 38,938 were in the accredited schools; and in the 109 such schools there were accepted in 1917 3,803 extra students owing to the efforts of this committee, which also recommended that theoretical instruction be crowded forward in order to release the graduates earlier for government service. It had also recommended that houses be rented and transportation provided when accommodations at camp hospitals were inadequate. The ideal was one nurse to every six acutely sick men with a reserve of twenty-five over the quota at each hospital. Miss Edna Goodrich was making a tour of inspection of every hospital in the United States.

Mrs. GREELEY addressed the meeting in connection with the application for military rank for nurses. She stated that the authority of nurses in wards in military hospitals was in serious danger, for the enlisted men often refused to obey orders. This resulted in friction, disturbed morale, and caused delay. The best way of handling the situation was to give some outward evidence of authority to the 9,000 nurses in the army. This would be limited to medical and sanitary matters in and about military hospitals and would also be subordinate to officers of the Medical Reserve Corps. No corresponding pay or other appurtenances were requested. The only valid objection to this scheme was that perhaps the matter could be handled by regulations. This was a matter for expert testimony.

Lieut.-Col. FRANK BILLINGS of Chicago presented the report of the Committee of Reconstruction. The sentiment was growing that the soldier disabled in war should be returned to civil life in as good condition as possible and not be condemned to the life of a mendicant or a dependent as happened so frequently after the Civil War. Soldiers should not be discharged from the army until all the resources at our command had been tried. Curative employment was one of the best of these; and this should be really useful. Basketry, knitting, etc., were all right in their places, but did not really fit a soldier to be self-supporting, nor did they make for self-respect. At present some ten

hospitals had had beds added to them for this work and six of them had furnished workshops. In the past three weeks 160 men had been started on their way to recovery.

Dr. ROSALIE MORTON, reporting for the Committee on Women Physicians, said there were 5,989 female physicians on the first list compiled by this committee and since that time 137 names had been added, making a total of 6,126, of whom 40 per cent. had registered for military service and had been catalogued according to their specialties.

Need of Medical Men for War Service.—The weekly reports of the Surgeon General's office indicate that the officers of the Medical Reserve Corps are being called to active duty faster than they are being enrolled. The Surgeon General's report for March 22 gives the total of 18,138 officers in the Medical Reserve Corps and of these 14,911 were on active duty. In order to acquaint the medical profession with the great need for physicians and surgeons for work in connection with the war representatives are being sent to various parts of the country to address medical meetings called by the State committees who are co-operating with Washington. Physicians who enroll are urged not to relinquish their practice until informed by the Surgeon General's Office that they are soon to be called to active service.

Casualties in April.—British casualties reported in April reached a total of 52,475, of which 1,621 officers and 7,723 men were killed or died of wounds, and 7,447 officers and 35,684 men were wounded or missing. A report from Washington authorizes the statement that during the week ended April 26, 113 sick and wounded soldiers returned from the American Expeditionary Forces were landed in the United States.

Health of American Army Camps.—A statement issued by Surgeon General Gorgas, on May 2, shows that death and sickness rates in the American Army camps are declining. The deaths for the last week in April numbered 251, as compared with 278 the preceding week.

Medical School Will Hold Summer Session.—In compliance with a request from the War Department to Dr. John A. Witherspoon, president of the faculty of the Medical Department of Vanderbilt University, the faculty has voted to continue the school session through the summer months. The War Department has made similar requests of other medical schools throughout the country. By a continuous school term the junior students will graduate four or five months earlier than otherwise, thereby releasing them for Government service.

Sentenced for Refusing Vaccination.—A drafted man from Goodrich, Minn., a member of the depot brigade, recently refused to submit to vaccination. He was tried by a general court martial and sentenced to fifteen years in the disciplinary barracks at Fort Leavenworth.

Women in Red Cross Relief Work.—An announcement made at the Red Cross Headquarters in Washington gives a list of forty-three women physicians from various parts of this country who are doing medical relief work in France and other countries. The American Red Cross has presented \$2,000,000 to the committee directing the French Red Cross, the Femmes de France, and the Dames Françaises.

MEDICAL RECORD.

CARDIAC RESERVE IN SURGICAL OPERATIONS.

CARDIAC efficiency for any purpose is measured not so much by the power it is able to generate for the usual activities of the body, no matter how great such demands may be, but rather by the amount of power it has in reserve to meet unusual demands. In prolonged diseases or in surgical operations the prognosis or the question of the surgical risk, as the case may be, depends upon the presence of such a reserve power and upon the disease or the operation called for. In myocardial, cardiovascular, renal, and other grave conditions that have a baneful effect upon the cardiovascular efficiency, the reserve power is usually very small, although the actual power of the heart is very large because so much power is required to drive the blood past the numerous obstructions or to supply extra demands. In such cases, except in emergencies, the wisdom of surgical operations with its general anesthesia becomes a very difficult question to decide. Although there is a vague understanding that in such conditions the reserve force of the heart is deficient, unless the fact can be definitely established with the relative amount of deficiency, such determinations are bound to be inaccurate and in so far valueless. Before a patient is refused surgical operation on this account it is essential to have a concrete understanding of the fact of this deficiency.

In normal individuals any exertion causes a rise in blood pressure, both of the systolic and the diastolic. The diastolic rises less than the systolic, but if the comparison is made between the blood-pressure readings before and after exertion this difference will be appreciated. In deficient reserve power there is a fall of blood pressure after exertion rather than a rise, as would be expected normally. It demonstrates the fact that the heart is unable to cope with the needs of extra exertion. There are shortness of breath, vertigo, fatigue, etc. This inability of the cardiovascular system to stand added strain must be determined before operations are undertaken because the strain of the anesthesia on the heart, the shock of the operation, all make extra demands upon the reserve force of the heart. If this is lacking sudden

death may be expected to follow—and without the slightest warnings of imminent danger. When all the actual and reserve power have been used up the heart simply ceases to functionate. These deaths are often attributed to unwise selection of the anesthetic or to pure shock, but are really the result of heart failure after unreasonable demands made upon the heart power by reason of the general anesthesia.

Cashman (*Amer. Journ. Med. Sci.*, 1917, pp. 476-489) suggests a method for determining the cardiac reserve power in order to anticipate heart failure during surgical operations under general anesthesia. He tests for the fall of blood pressure after mild exertion before undertaking any but emergency surgical operations, especially in those in whom there is gross evidence of the possibility of this deficiency, although the routine measuring of every surgical case is advisable. Both the systolic and the diastolic pressures are measured in the recumbent position, standing, and after exertion of a mild sort. In normal individuals there is a rise in blood pressure even on merely changing from the recumbent to the standing position. In patients with deficient reserve force there is, on changing from the recumbent position, or more on mild exercise, a greater or lesser degree of depression of the blood pressure. It is this type of patient, so sensitive even to mild strain, in whom the large strain upon the heart caused by surgical anesthesia is often unbearable and followed by fatal results. Where there are already gross cardiac irregularities due to disease this test cannot be applied, nor is it necessary to show by these methods that there is such a deficiency. When it is determined that the cardiac reserve force is below the limits of safety, necessary surgical operations must be performed under local or spinal anesthesia whenever possible.

A SPECIAL FORM OF STAPHYLOCOCCUS INFECTION.

NOLF, Bossaert, and Colard describe in the *Archives médicales Belges* for January a condition which at first escaped diagnosis—a non-contagious general infection which might conceivably pass for typhoid fever during an epidemic of the latter. The fever, however, appears suddenly in the midst of apparent health with the usual accompaniments of headache, prostration, pains in the limbs, anorexia, febrile urine, etc. It is of course easy to call such cases grippe or, if the digestive tract suffers especially, febrile gastric catarrh. The respiratory system remains intact throughout. A diagnosis of typhoid fever would not be thought of in the absence of an epidemic and among the vaccinated soldiery, although we cannot ignore the existence of rare cases of mild typhoid in the latter in which the intestine does not appear to be involved and in which hemoculture is often negative.

In searching the various body fluids and secretions for the typhoid bacillus the authors frequently stumbled upon a form of *Staphylococcus pyogenes*,

especially in the urine. Clinically no symptom stands out with such prominence as to implicate any one set of organs. The severe headache often present was never accompanied with nausea or vomiting. The fever rose to 104° F. without any typical curve. The spleen was as a rule somewhat enlarged. Only when the skin is reached do we find anything suggestive—pustules or boils, or at times non-pustular exanthems. When the skin is free there may be an angina. If staphylococci are absorbed from the skin and eliminated by the kidneys, as seems to be the case, they cannot always be found in the blood, nor do they set up any urinary symptoms—doubtless because present in such small numbers. There is no bacteriuria. The blood counts throw no light on the nature of the affection, even when hemoculture was positive for staphylococci, there were often no noteworthy changes. As would be expected hemocultures were most often positive in cases where high fever persisted after admission into the wards. The total number treated was 24. While some of these cases were mild others partook of the nature of clinical sepsis. Between a mere febricula lasting but a few days and severe septicopyemia there were various gradations of severity.

The authors are interested chiefly in the types which have not hitherto been recognized clinically—for staphylococcus sepsis and metastatic lesions are sufficiently well known. Such types correspond to the milder cases in which the germs at most caused a brief toxicosis, not pronounced enough to modify the blood picture, and unattended with secondary foci. To make a diagnosis in such cases we must depend chiefly on the uranalysis, for hemoculture is mostly negative, even with great technical refinements. Failure to recognize the nature of these cases might give rise to false beliefs—for example in the existence of post-vaccination typhoid or of some masked contagious affection.

STREPTOCOCCAL IMPETIGO AND ACUTE NEPHRITIS.

It is well known that acute nephritis is by no means an infrequent complication or sequence of scarlatina. In the *Practitioner* for April, 1918, Dr. W. Fletcher Stiell expresses his conviction that many cases of acute nephritis, for which formerly no definite causative factor could be assigned, are in reality a complication to an ordinary attack of contagious impetigo. His argument is as follows, that as impetigo contagiosa is simply the result of an accidental inoculation of the *Streptococcus pyogenes* beneath the skin, it is not very surprising to find that this disease can be followed by a nephritis identical with that following scarlatina. The analogy runs somewhat in this fashion: If it be admitted that scarlatina is itself a streptococcal septicemia with a primary seat of infection in the tonsils or lungs, then if there is some slight difference in the actual strain and virulence of the organism and its mode of inoculation there is still

sufficient similarity in the kind of infection and manner of inoculation to demonstrate a close association in the causation of both impetigo and scarlatina. Moreover, Stiell, as the result of his own observations, is of the opinion that not only is true streptococcal impetigo contagious but also infectious.

As in scarlatina, an acute case of nephritis may occur in impetigo without any definite signs of a generalized streptococcal septicemia. Albuminuria usually manifests itself for the first time at least a week after all pyrexia has vanished and septicemia has presumably subsided.

Five cases of acute nephritis resulting from typical impetigo contagiosa are briefly outlined and from an analysis of these cases Stiell draws these deductions. It seems probable that an acute streptococcal impetigo is capable of producing an acute nephritis, every whit as severe as that following an ordinary attack of scarlatina. It is not to be inferred that every case of impetigo will subsequently develop nephritis, but it is Stiell's belief that the risk of such an occurrence is quite as great as in scarlatina. Furthermore, he suggests that many of the cases of so-called "trench nephritis" in soldiers are, in fact, a complication either of an impetiginous pediculosis or an impetiginous scabies. In this connection it is interesting to note that in the British army cases of nephritis have now been made notifiable as a "contagious disease." It is not stated whether it is the actual nephritis, which is to be regarded as contagious or whether it is the cause of the nephritis. This seems to be a matter which should be made clear.

Stiell's theory appears to be not only extremely plausible, but supported by clinical evidence.

A NEW METHOD OF DIAGNOSIS OF DEATH ON THE BATTLEFIELD.

LECHA-MARZO, an ophthalmologist of Seville, contributes an article on this subject to the *Archives Médicales Belges* for March. The author is not engaged in military activities, and his method has been studied in civil practice. He begins with the work of Icard, which seeks to prevent the possibility of burial alive by recognizing the signs of life; and that of Thoinot, who searches for signs of death; for the two fields are by no means co-terminous, even if a sign of life be inverted to a sign of death, and *vice versa*. The true signs of death are all slow to appear, so that recognition of life in apparent death has been the more hopeful study. First should be mentioned the Hallum test for life—the instillation of a 20 per cent. solution of dionine into the conjunctival sac. If life is still present, there should appear in a few moments congestion, lacrymation, and chemosis. But it is not necessary to bother with dionine, for sulphuric ether will give the same reaction. This resource has never had a thorough tryout; other tests also rest on the integrity of the circulatory functions,

and in particular the fluorescein test of Icard. Much was at first hoped from this resource, but it was shown to be fallacious, in that it gave negative results in subjects proved to have been alive. In other words, circulatory insufficiency need not straightway mean death. Icard next introduced a sign of death, to wit, the staining of paper soaked in sugar-of-lead solution, when placed in the nostril, as a result of the liberation of sulphur in early decomposition of certain tissues. The present author showed that this reaction can occur in the living, while it may only appear in the dead at a late date. Several death tests based on the appearance of an acid reaction in the viscera have not made good in practice.

The author now submits his very simple test of death, which is likewise based on the change of reaction after death. The tissues and secretions of the eye are at first alkaline, then amphoteric, and finally acid. While other tissues have been known to again become alkaline after acidity, this has never been seen in the eye, so that ocular acidity is proof of death. Moreover, in almost every case this acidity is precocious, appearing within the first eight hours. It has been recognized as early as a half hour after death. In this connection, at the author's eye clinic the tears have been tested in over 1100 patients with various eye diseases, and in not a single instance was an acid reaction obtained. To practise the test, place a piece of litmus paper on the globe of the eye, beneath the lids, and then compress the latter. In the living subject the paper at once turns blue. If the subject is a cadaver there is either no change in the paper, or else a marked rose color appears.

THE DEAN OF AMERICAN INTERNISTS.

DR. ABRAHAM JACOBI celebrated his eighty-eighth birthday on Monday of this week. He was born at Hartum, in Westphalia, and was graduated in medicine from the University of Bonn in 1851. He began his long career of service to humanity in revolt against the iniquitous Prussian government, being perhaps the first man among those living today to attempt to "can the Kaiser"; he failed, and the Kaiser's ancestor canned him, and kept him in detention in Berlin and Cologne for two years on the charge of high treason. Perhaps had he succeeded in that laudable endeavor, Germany would now be as decent as the rest of the world and the present war would not have been. In spite of what he had tried to do to reform her, Germany felt she could not get along without him, and called him to the chair of medicine at Berlin some twenty or twenty-five years ago. Fortunately, he resisted the temptation, if temptation it was, and remained with us. Almost every local and national medical society of which he was a member has at some time elected Dr. Jacobi as its presiding officer, and the MEDICAL RECORD congratulates itself on having had the honor of nominating him to the presidency of the American Medical Association, his election occurring at the next meeting, in Los Angeles, in 1911. Mayor Hyman recently contributed not a little

to the gaiety of the town by demanding that Dr. Jacobi be dropped from the advisory health board for the reason that he had a son-in-law who was supposed not to think much of the Mayor. And thus, both directly and indirectly, this fine old gentleman lightens the tedium of our existence. The MEDICAL RECORD joins the other friends of Dr. Jacobi in wishing him yet many years of usefulness.

IS ECLAMPSIA A CONSEQUENCE OF INCREASED INTRACRANIAL PRESSURE?

IN uremia, cerebral edema is known to occur, while in eclampsia it is not found at autopsy. Zangemeister, who has done decompression operations on eclamptics, has, however, never failed to find it *intra vitam* (abstract in *Correspondenz Blatt fuer Schweizer Aerzte*, January 26, p. 122). Since all known theories of eclampsia causation fall short, this author endeavors to build up a case in favor of intracranial tension. The presence of increased fluid within the cranium is readily explained by the general tendency in late pregnancy to edema. The latter is seldom of renal origin, and we have no inkling as to why it affects the brain of one woman and not that of others. This increase of tension will readily account for the various symptoms of eclampsia, and whether a toxemia is the original moment in determining increase of tension may be left undecided. The mechanism doubtless comprises an excitation of the vasomotor nervous system. At the same time, Zangemeister would not claim that his theory exhausts the subject of the causation of eclampsia, but at the least it must be an important link in the chain. The success of various plans of treatment is in full accord with his theory, and he does not claim that decompression is an operation of necessity. He does not refer to the occasional successes ascribed to lumbar puncture. A prophylaxis directed against cerebral edema must be insisted upon, although no special recommendations are given.

News of the Week.

Nursing Service Cares for Record Number of Pneumonia Cases.—The Henry Street Settlement, New York City, announces that the large number of pneumonia cases in March caused a record number of calls on its nursing service. There were 6,868 patients reported to the service and 30,450 visits made, an increase of about 5,000 visits over March, 1917. Of these cases 1,050 were pneumonia and the percentage of deaths rose from 8.7 in 1917 to 12.3 in March, 1918. Much of the work was carried on in families of men in the Army; the nurses took these patients under the direction of the Red Cross.

Decrease in Automobile Accidents.—The report of the National Highways Association for the month of April, 1918, shows that 45 persons were killed by automobiles in the State of New York during the month, a decrease of 22 over the same period of 1917. In New York City, 29 persons were killed by automobiles, seven by trolley and five by wagons, as compared with 38 by automobiles, seven by trolley, and nine by wagon, in the corresponding month

of the preceding year. Ten persons were killed at grade crossings during the month.

Women's State Medical Society.—The twelfth annual meeting of the Women's Medical Society of New York State will be held Monday, May 20, 1918, at the TenEyck Hotel, Albany. Not only members but all women are welcome. The date and place are chosen so as to make it convenient for the members, many of whom are also members of Medical Society of the State of New York, to attend the annual meeting of the latter which opens the following day.

Developments in Health Department Shake-up.—The first official act of New York City's new Health Commissioner, Dr. Royal S. Copeland, was to suspend Dr. Lucius P. Brown, pending his trial on charges made by Dr. Copeland. The reasons given for Dr. Brown's suspension are that he made public a reply to the attack on his conduct of the Bureau of Foods and Drugs by Chairman James E. McBride of the Civil Service Commission. Dr. Brown's trial will be public and conducted before the Board of Health, which consists of the Health Commissioner, the Police Commissioner, and the Health Officer of the Port. Dr. Copeland finds the bureaus assailed by Mayor Hylan "magnificently handled," and fails to uphold Mr. McBride. He has declared his intention of keeping up the fight on nostrums and states that in his opinion public health education is a vital function of the Health Department. The Committee on Wartime Problems of Childhood of the New York Academy of Medicine, after a conference, framed resolutions which were sent to Dr. Amster, congratulating and applauding him for the courageous stand he had taken in refusing to be a party to the attempted spoliation of the Health Department. The Citizens' Union also sent resolutions to Dr. Amster, recording their appreciation of the courage and wisdom displayed in his struggle to preserve the agencies of the Health Department from threatened destruction. Mayor Hylan, in the meantime, has wisely retired from the contest, reversing himself on every point, evidently thinking it about time to "give a darn for those federal government letters." Dr. Charles F. Bolduan, head of the Bureau of Public Health Education, has tendered his resignation. Dr. Copeland is quoted as saying, in regard to this, that Dr. Bolduan is being punished for having followed Commissioner Emerson's orders, based upon the latter's "impractical idealism."

Still Another Investigation.—Commissioner Coler of the Charities Department of New York City is conducting an investigation of the city institutions on Randall's Island. It is alleged that "the condition in which the former administration left the children there is a disgrace."

The Medical and Chirurgical Faculty of Maryland held its annual meeting at Osler Hall, Johns Hopkins University, on April 24. Dr. William W. Keen of Philadelphia, who was scheduled for an address on Surgery, said he could not speak on that subject, that there was but one subject he could discuss with such a crisis confronting the Government, and that was the necessity of crushing the Hun. An interesting feature of the meeting was the presentation of oil portraits of the late Dr. Thomas R. Latimer and Dr. Isaac R. Trimble which

are to be hung in Osler Hall. The following officers were elected for the ensuing year: *President*, Dr. John Ruräh; *Vice-presidents*, Drs. J. Bergland, Philip Briscoe, and J. E. Deets; *Secretary*, Dr. John Staige Davis; *Treasurer*, Dr. William S. Gardner.

Charitable Bequests.—Among numerous bequests made by the will of Mrs. Margaret E. Zimmerman are the following: The New York Asylum for the Blind, \$5,000; New York Nursery and Child's Hospital, \$20,000; General Memorial Hospital for the Cure of Cancer and Allied Diseases, \$50,000.

Medical Society Elections.—THE CALIFORNIA STATE MEDICAL ASSOCIATION, at its meeting in Del Monte on April 17, 18, and 19, elected the following officers for the ensuing year: *President*, Dr. Cornelius Van Zwahlenberg of Riverside; *Vice-president*, Dr. John Graves of San Francisco; *Secretary-treasurer*, Dr. Faxton Pope of San Francisco.

THE TOLLAND COUNTY (CONN.) MEDICAL ASSOCIATION, at its meeting in Rockville, on April 18, elected the following officers: *President*, W. L. Higgins of South Coventry; *Vice-president*, Dr. R. L. Hurd of Somers; *Secretary and Treasurer*, Dr. F. W. Walsh of Rockville; *Councilor*, Dr. Thomas F. Rockwell of Rockville.

THE WORCESTER (MASS.) NORTH MEDICAL SOCIETY, at its meeting on April 23, elected the following officers: *President*, Dr. A. P. Lowell; *Vice-President*, Dr. C. E. Woods of Lunenburg; *Secretary*, Dr. F. M. McMurray.

THE MEDICAL ASSOCIATION OF GEORGIA, which met in Savannah on April 18, 19, and 20, elected the following officers to serve for the ensuing year: *President*, Dr. J. W. Palmer of Ailey; *First Vice-president*, Dr. George R. White of Savannah; *Second Vice-president*, Dr. L. B. Clark of Atlanta; *Secretary-treasurer*, Dr. W. C. Lyle of Augusta.

THE WINDHAM COUNTY MEDICAL SOCIETY, at its one hundred and twenty-fifth annual meeting in Willimantic, on April 20, elected the following officers: *President*, Dr. Ernest R. Pike of East Woodstock; *Vice-president*, Dr. J. A. Girouard of Willimantic; *Secretary and Treasurer*, Dr. A. D. Marsh of Hampton; *Counselloer*, Dr. R. C. White of Willimantic.

THE CONNECTICUT SOCIETY OF PHYSICAL EDUCATION, recently organized in New Haven, has elected as its *President*, Dr. E. H. Arnold of New Haven and as *Secretary*, Dr. F. E. Foretch.

Scout Camp Physicians.—A medical man is wanted to look after the health of a Scout camp of 750 boys from July 1 to September 1. Information regarding requirements and salary may be obtained from C. Elmore Smith, 59 Wall Street, New York.

Special Clinic for Syphilis.—The New York Skin and Cancer Hospital has inaugurated a syphilitic clinic on Tuesdays, Thursdays and Saturdays from 11 A. M. to 1 P. M., in addition to the daily clinics on dermatology and surgery; also on Monday and Thursday evenings from 8 to 9, only for the poor employed during the day.

Physicians Needed in New York Dispensaries.—At the meeting of the New York Academy of Medicine, on May 2, the Public Health Committee of the Academy, through its Chairman, Dr. Charles L. Dana, made an appeal to physicians who have had

dispensary experience but who at present have no dispensary affiliations and who because of age or for other reasons are not available for military service, to volunteer for dispensary duties as their contribution to the war. Dr. Dana stated that the withdrawing of physicians from civil life into military service has created a shortage of men in the dispensaries of New York, resulting in a curtailment of the services of these institutions, and that when subsequent calls are made upon the medical profession the dispensary service will be still further decreased unless steps are taken to provide substitutes for those called to Government service. The Boston dispensaries have been confronted by a similar problem and are meeting it by calling on the older men to volunteer for dispensary work.

New Public Health Law.—The Whitney Measure, which was passed by the New York State Legislature at the request of the Federal Government, went into effect on May 3. This law is described as the most drastic public health law ever enacted by any State in this country. It provides for the arrest and detention of persons afflicted with venereal disease, and is designed for the protection of soldiers and sailors. Under this law officials of the City Health Department are sent into the Night Courts to see that the law is enforced. The Health Department announces that men are arrested as well as women.

Obituary Notes.—Dr. EPHRAIM FLETCHER INGALLS of Chicago died on April 30, of angina pectoris. He was born in Lee Center, Ill., and was graduated from Rush Medical College in 1871. Immediately after graduation he became associated with the teaching staff of Rush, and maintained his connection therewith until his death. He also held teaching positions at various times in the Northwestern Women's Medical School and the Chicago Polyclinic. Besides being professor of diseases of the chest, throat, and nose, he was comptroller of Rush Medical School for the past twenty years. He was a member of many special and local societies and also of the American Medical Association. He was the author of a well-known treatise on "Diseases of the Chest, Throat, and Nose," and of many contributions to medical journals.

Dr. GEORGE FREDERICK BROOKS died at his home in New York City on April 26, aged 60 years. He was a graduate of the Medical Department of New York University, in 1880, a member of the New York Academy of Medicine, and chief examining physician on one of the local draft boards.

Dr. JEREMIAH EVERETT MCSWEENEY, a graduate of the University of Vermont, in 1891, died at his home in Hartford, Conn., on April 15, aged 52 years. Dr. McSweeney formerly resided in Barre, Vt.

Dr. WEEMS R. WINCHESTER of Macon, Ga., died of a stroke of paralysis, on April 15, aged 70 years. He was a graduate of the University of Maryland College of Medicine in 1874.

Dr. GABRIEL H. WADKINS of Hollow Rock, Tenn., died at his winter home in Clearwater, Fla., on April 18, aged 73 years. He was a graduate of Vanderbilt University Medical Department, Nashville, in 1877, and served in the Confederate Army during the Civil War.

Dr. FREDERICK BLUME, a graduate of the Medical Department of the University of Georgia, in 1877,

and a member of the staff of the Alleghany Hospital, died at his home in Pittsburgh, Pa., on April 14, aged 68 years.

Dr. EDWIN P. CLARK, a graduate of the Medical Department of the University of Pennsylvania, in 1857, died at his home in The Plains, Fauquier County, Va., on April 14, aged 85 years.

Dr. GEORGE DAVIE FYFE, a graduate of the New York University Medical School, in 1896, died of pneumonia at his home in Jersey City, on April 26, aged 48 years.

Dr. HENRY D. NICHOLS, a graduate of the Medical Department of the University of Pennsylvania, in 1898, died at his home in Douglas, Ariz., aged 47 years. Dr. Nichols practised medicine in Philadelphia and Atlantic City before removing to the Southwest.

Dr. H. B. GOODEBY, a retired physician of College Park, Ga., died, on April 9, at the age of 86 years.

Dr. ADELBERT DALTON ATWOOD of Brooklyn, a graduate of the Buffalo Medical School, in 1879, and for many years connected with the Brooklyn Board of Health, died on April 28, aged 68 years.

Dr. PAUL N. LITCHFIELD of Camden, N. J., died of pneumonia on May 1, aged 45 years. He was a graduate of Jefferson Medical College, in 1895, and at the time of his death was a member of the New Jersey Assembly.

Dr. EDGAR SNYDER of Edgewater, Col., died in St. Anthony's Hospital, Denver, on April 17, aged 69 years. He was a graduate of Rush Medical College, Chicago, in 1876.

Dr. TIMOTHY ROSE GROW, a graduate of Hahnemann Medical College and Hospital, Chicago, in 1877, died at his home in Lynn, Mass., on April 23, aged 78 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

MEDICAL MEN AND MILITARY SERVICE—IMPERSONATION AND MEDICAL COMMISSIONS—NEW ADVISORY BOARD OF THE ARMY MEDICAL SERVICE—RELIQUÆ OF JAMES PEDDIE STEELE—THE LATE DR. PROSSER JAMES—THE LATE PROFESSOR A. N. CARTER.

LONDON, April 11, 1918.

THE course of military events on the Western Front has led to the necessity of an immediate further strengthening of the man-power of the British army, and on April 9 the Prime Minister introduced into the House of Commons a bill raising the military age to 50, the first sub-section of the first clause setting a still higher age limit for medical men, and enacting that as regards any duly qualified medical practitioner the limit of age shall be "not exceeding 56." The members of the British medical profession have shown such patriotic willingness to serve their country in any military capacity upon the original voluntary basis, and through the organization of the Central Medical War Committee have so freely replenished the *cadres* of medical officers in the navy and army, as the exigencies of war demanded, that there is no doubt the same spirit will prevail in face of this last and very heavy demand. But the care of the civilian population will require strenuous work owing to the diminished number of doctors.

The new man-power bill, which places the age for military service between the years of 18 and 50 inclusive for all males, also provides, as has just been said, for the extension of this term of 55 years in the case of certain professional callings; and the one instance of such callings given in the House of Commons by Mr. Lloyd George when introducing the bill was naturally the profession of medicine, as the want of doctors with the navy and army is keenly felt when it regularly occurs. The age limit for doctors was accordingly raised to 55. Several episodes dating from before the war, some from its commencement, and some fairly recent, have led to the belief in the minds of people who have reason to know 'that it will be necessary to scrutinize closely the medical candidates for commissions, who are being at the same time urgently entreated to come forward. There is undoubtedly a considerable chance of successful impersonation at the present moment, and while it is unlikely that any medical man over 50 years of age, save at his own express desire, will be sent to the front, a successful impersonator would obtain rank, pay, and consideration, perhaps prestige, without running any risk whatever. The ordinary safeguard against impersonation is, of course, the Medical Register, the official roll on which a man's name is entered when he has obtained the necessary certificates showing that he is entitled to call himself a qualified practitioner, paying at the same time £5. Then for the rest of his life his name is on the Register, and the date of his qualifications affixed, while he carries away a receipt in his pocket, which more often than not he loses sight of, and it passes into any one's possession. In a London surgery I have seen two certificates hanging framed on the premises, the owners having left them behind for any improper use which they might serve. In normal times, for a man to carry on business as if he were some one else entails considerable risk. The real man is in existence somewhere, and at any time might communicate with the general Medical Council who keep the Register. But all this is altered in times of war, because the masquerader can boldly state that he is another man of the same name, over from the colonies, who has never troubled to register. The medical profession is in a flux. Men are doing each other's duties all over the country, as well as serving in the armies in the Far East, the East and the West, by sea and by land. As a rule, if a man said he was John Smith of Norwich, say, one could write to John Smith at Norwich, if doubt arose. But to-day John Smith of Norwich would not be at Norwich—the impersonator would make it his business to know that—and if you did not know John Smith by sight you could not find out that you were dealing with his impersonator. Also there are American and Canadian medical men doing duty at our hospitals who are not necessarily known to each other, any more than to our authorities. An impersonator claiming to be a Canadian or an American might not throw off all suspicion, but before his game was up he could vanish. Bearing all this in mind, and considering the danger which might be entailed by allowing impersonation to occur in the medical service of the army, it has been seriously suggested that on registration all British medical men should have their finger prints

officially taken. The suggestion was first made two or three months ago, at a time when a man named Siddons, who had been trained in veterinary medicine, managed to impersonate a medical man who had been drowned abroad, and whose death had not been notified for removal of his name from the Medical Register. Siddons, in this man's name, practised medicine with considerable success, and sat upon one of the recruiting boards, acting for a time as chairman. He was eventually detected, was found to have committed the same crime before, and destroyed himself while in prison. His impersonation was successful for a serious period of time, and resulted in a large number of bogus certificates, but a real medical member of the recruiting board on which Siddons sat testified that Siddons' professional eye as a veterinary surgeon made him a good rough judge of the physical quality of a man.

The Advisory Board of the Army Medical Service has been reconstituted, smaller in size, and in more direct application to its duties. The new board is composed of Sir Bertrand Dawson, a major general in the R. A. N. C. and physician to the London Hospital; Sir Berkeley Moynihan, also a surgeon-general, and professor of clinical surgery at Leeds University; Sir Robert Jones, a well-known Liverpool surgeon, who came early to the fore as an orthopedic surgeon, and is now Director-General of Military Orthopedic Surgery; Colonel Sir Harold Stiles, the leading operating surgeon in Edinburgh; and Colonel W. H. Horrocks, R. A. N. C., a famous expert in sanitation generally, and especially in the military development of his department, and the only member of the board just disbanded. The board will be presided over by the Director-General of the Army Medical Service, Surgeon-General Goodwin, who is well known to all the American medical officers; and the same may be said of Sir Berkeley Moynihan, who has latterly been on particular service with the Army Medical Corps of the United States. It is a strong board, and the probability is that Surgeon-General Goodwin will have reason to be glad that he has such a sound advisory body behind him. Sir Alfred Keogh, Surgeon-General Goodwin's predecessor, had the vast experience given by occupying a similar position in a previous war; upon this he could always draw, and leave his advisory board, also a good one, to discharge their separate medical functions almost undisturbed. He was sometimes criticised for the independence of his actions, and this would have been avoided had his critics known how regularly he was in informal communication with his advisers.

Prof. John Harrower, writing from the Greek Manse, Aberdeen, introduces to a classical medical audience a charming selection of Latin exercises by the late Dr. James Peddie Steele. Steele was a graduate in medicine of the University of Edinburgh, but his earliest academic work was done in the classics, and at one time he acted as assistant to the famous Professor Blackie, professor of Greek at Edinburgh. Medicine, however, attracted him, and after graduation he came to London to establish himself in private practice. Literary employment, as it chanced, came to his door much more frequently than patients, and within two years of his arrival in London he was a regular leader writer

on two or three important daily papers, London and provincial, as well as one of the principal editorial writers in *The Lancet*. While on the staff of *The Lancet* he was invited to Rome, where a very good opening for practice had occurred. He went, and lived for forty years in Italy, dying there last autumn. For the first twenty years he practised as a physician in Rome; for the last twenty he lived at his beautiful Florentine villa, or in the old monastery of San Antonio at Tivoli. During all the period of his retirement he was devoted to the study of Latin and Greek. He offered prizes and founded scholarships in connection with classics, and was a generous patron of the British School of Archaeology in Rome. Late in life he became assiduous in the composition of Latin verse, using elegiacs, alcaics, and sapphics with equal facility, and achieving on many occasions a wonderful Horatian illusion. Professor Harrower has brought together in book form some twenty of these charming little pieces, and it seems a pity that they should only be available for private friends. The love of elegant scholarship is not dead at any rate among English and Scottish medical men, and many of these would delight in Steele's polished Latinity.

The death occurred on April 6 of Dr. Prosser James, at the advanced age of 82. He had retired from the practice of medicine for some years, but in the 'seventies and 'eighties his activities were manifest in many directions. Moses Prosser James received his medical education at the London Hospital, but took opportunities of revising his knowledge at various continental medical schools, those of Lyons and Barcelona among others. He qualified over 60 years ago as M. R. C. S. Eng., but later graduated in medicine at the University of St. Andrews, and took the M. R. C. P. London in 1867. He was for a time lecturer in *Materia Medica* at the Medical School of the London Hospital, and on the foundation of the Hospital for Diseases of the Throat in Golden Square became physician to the institution, being at the same time physician to the Children's Hospital, Victoria Park, in the north of London, and physician also to the North London Hospital for Consumption. Relying on these various clinical opportunities, he published in 1884 a treatise on the "Therapeutics of the Respiratory Passages," and two works, illustrated in colors, upon affections of the throat, rhinoscopy, and laryngoscopy. Both treatises achieved the success of several editions, and much of their information was afterward condensed in the article on diseases of the throat contributed by Dr. James to the *Twentieth Century Practice of Medicine*. He was also an authority on the use of mineral waters in medicine, wrote a small work on the therapeutical resources of Vichy, and jointly with Professor Tichborne a larger book, entitled "The Mineral Waters of Europe." He was a man of considerable general accomplishments, and for very many years furnished the *MEDICAL RECORD* with a weekly London letter.

The death occurred in the same week of Professor Alfred Carter, professor of medicine in the University of Birmingham, and author of "The Elements of Medicine," a handbook which has been in popular use among British medical students for 30 years, a new edition having appeared as recently as 1912. The book was not designed by the author to supersede the larger manuals and systems of medicine,

but so adroitly do its contents summarize the essentials of medical knowledge that many students have successfully passed their examinations on "Carter," when they have used their clinical chances well, also.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

THE WORK OF THE RED CROSS IN SAVING THE CHILDREN OF FRANCE—ENCOURAGING PLAY AND TEACHING GAMES.

PARIS, April 1, 1918.

DR. WILLIAM PALMER LUCAS, chief of the Children's Bureau of the American Red Cross, believes that play counts as much for the development of a child as text books. The Red Cross has opened playgrounds in several of its children's homes, because they believe that games are just as important a part of education as anything that the child gets in school.

Organized games teach teamwork; they are not just physical exercise. A child learns cooperation with his fellows. This training in cooperation and reliance on teamwork learned on the playground is one of the greatest assets a man can have in business. Play breaks down petty personalities. You learn to respect the man who can play the game, even though you don't like him personally. That expression, play the game, is not just slang; there is a real reason for its hold on the American imagination.

The Red Cross got interested in play here in France because it was discovered that since the war most of the Paris playgrounds (there were never very many of them) have been closed. They found Miss Maud Cleveland, formerly physical play director at the University of California, as an aid at the Neuilly Hospital. She studied the situation here, and made some suggestions as to the kinds of games French children were used to play and what outdoor games could be introduced. Then she went to Toul, where she has been organizing play for the 430 children in the refuge there who come from the gas-bombed villages just behind the front.

Dr. Wilson, with some volunteer workers, has been teaching football and baseball to the boys in the Franco-American colony at Issy, and the boys get up early in the morning to practise.

They have two young men from the American Friends' Unit leading play at Le Glandier, the big refuge for 600 Belgian children in the corrèze. People have always said that French children didn't like American games. It isn't so. There are so many children at Le Glandier that half of them have schools in the morning and half in the afternoon; the other half day they pass on the playground. They play football and baseball, tag, prisoner's base; they have running and jumping contests and throwing the medicine ball.

One interesting thing that is coming out of this play is that the boys and girls play together. At first there was opposition to it, but it works. The little girls play just as well as the boys; they show just as much initiative and teamwork. Of course, this sort of coeducational play is the real basis of the American interrelation of sexes. It breaks down false ideas of separation and puts them on a more solid and firmer footing with each other.

In all social circles the two sexes are kept rigorously separated. A young lady of good family is never seen alone upon the street; either a member of her family or a domestic accompanies her, and she is never permitted to receive alone the visit of a male acquaintance in her own home. Always some third person is present, so one can more readily understand the revolutionary innovation of permitting children of the two sexes to play together freely.

Play ought to be developed in connection with all such work. It has been proved that the children do better and more work rather than less; they show more alertness and acumen when they have short, intermittent periods of play. The Red Cross is arranging to give a whole section to recreation in an exhibit it is going to give in one of the big cities this spring to demonstrate types of American play and games that can be adapted over here. Then it proposes to have a big playground, a sort of summer camp, near this town, and American playground workers have been sent for to come over and help them.

To leave the little refugee children idle, dispirited and playless is just as bad as to leave them hungry.

5. The Modern Treatment of Tuberculosis.

3. Surgical Sutures as Cause of Wound Infection.—W. H. Watters believes that if due care is exercised in the handling and employment of surgical sutures, ordinary wound infection due to this material may be entirely disregarded. He considers that the danger lies in the improper handling of the sutures after they leave the sealed container and, if the suture is tied too tightly, in the development of some slightly virulent skin staphylococci in the resultant improperly nourished tissues. He points out that catgut, each length of which represents all that is left of an equal length of sheep's intestine, is the most difficult suture to sterilize, as the tube cannot be laid open. Consequently, it is essential that measures of sufficient power be used positively to kill every form of bacterial life. While most bacteria succumb to a short exposure to 65° to 70° C., many spores can withstand a temperature of 120°, 130°, or even 145° C., for a certain time, and all sutures therefore must be subjected to conditions definitely fatal to anthrax and tetanus spores and thereafter protected from any possible infection. In wound infection the bacteria groups represented are the staphylococci, the streptococci, and the colon bacilli. All these organisms are readily and easily eliminated by thermal or chemical means, but it must be remembered that measures which are effectual against pyogenic organisms are not capable of destroying all spore-bearing bacilli and unless attention is paid to this point, tetanus or other disease is bound to appear.

2. Trench Sanitation. Captain C. E. Burt.
3. Prevention in Public Health. D. M. Lewis.
4. Progress in Gynecology. Stephen Rushmore.

2. Trench Sanitation.—Captain C. E. Burt divides the vital things to be considered in trench sanitation

into five headings, namely: Food, water, conservancy, personal habits, and prevention of special diseases. He points out the value of the fireless cooker in the preparation of food, and the traveling kitchen or field cooker in the zone of the advance; the latter weighs twenty-four hundred pounds and cooks for two hundred and fifty men and their officers. The medical officer is charged with the following details: quality, variety, and cleanliness of rations and stores; quality and variety of cooking; cleanliness in delivery, preparation and sources of food; health of all persons issuing, preparing, or serving food; protection of kitchens from dirt and dust; daily inspection of towels. The water supply should be sterilized by boiling or with calcium hypochlorite; the Lister bag may be used. Cavalry soldiers are supplied with sterilizing tablets for use in the water bottles. A reasonable amount of water and basins should be provided for washing purposes, and even shower baths should be installed in a deep shelter. Under the head of Conservancy, Burt describes some of the devices employed to meet conditions in trench warfare and states that the only practical solution of the problem has been found in the system adopted by the British—the use of bomb-proof pits or dugouts leading out of the communicating trenches. The dugouts should be deep enough to protect against any missiles except high-explosive shells. A pit is dug and covered with a latrine seat. Excreta is collected in small buckets, empty gasoline tins, or other receptacles, which are set in boxes with a sliding cover, or else have a detachable seat and a cover hinged with leather, to make them fly proof. The receptacles when two-thirds full are removed by relieved troops and their contents buried, the buckets cleaned and brought back by the troops on their return. The latrines must be disinfected daily by a man from the medical department, the disinfectants used being sulphate of iron 10 per cent., cresol 5 per cent., and unslaked lime or milk of lime. Urine soakage pits and funnels are useful; all soiled areas should be treated twice daily with a 5 per cent. cresol solution. Burt states that the discovery during the war that the body louse is the transmitting agent of typhus fever makes it important that every effort be made by the Sanitary Corps to afford facilities for the necessary delousing of troops. Provision must be made for systematic bathing of all the men when they return to camp, and in order to do this on the Western front, one hundred and sixty men must be bathed per hour for nine hours a day if each man in the division is to receive a bath once every two weeks. Clothes are disinfected by sterilization and ironing is relied upon to rid them of lice. For personal use, a powder known as N. C. I. is dusted on the underclothing and has proved effective. It is composed of naphthalene, 96 parts; creosote, 2 parts; iodoform, 2 parts. About two-thirds of an ounce is required for each man. An ointment composed of crude mineral oil, 9 parts; soft soap, 5 parts; and water, 1 part, asphyxiates the young lice as they hatch out of the ova. This is rubbed into the interior seams of the various articles of clothing in the quantity of about one ounce per week. The body from the neck down may be anointed with this paste. Underclothing may also be dipped and wrung out in a solution of 1 per cent. each of naphthalene and sulphur in benzine or gasoline. This is the English "antiparasitic" vest and is not especially irritating to the skin. Burt states that the condition known as trench feet can be largely prevented by the following precautions: 1. Boots and shoes should be at least a size too large, so that two pairs of socks may be worn. 2. Rubber hip boots should be furnished if there is standing water in the trenches. 3. General circulation must be kept up by keeping body warm and dry. Wear waterproof clothing, especially in rains. 4. Every 24 hours the boots should be removed, the feet rubbed and dried, and dry socks put on. 5. Thorough rubbing into the feet and legs of whale oil or anti-frostbite grease. 6. If rubber boots are not worn, the boots should be well oiled or greased. 7. Drainage of trench or dry standing provided. Avoid standing still as much as possible. 8. Keeping the legs elevated while resting, and the avoidance of the sitting posture in sleeping. 9. Avoid fatigue by keeping up the physical condition of the soldiers by proper nourishment and warmth. Frequent use of hot soups and rum fills the bill. 10. Puttees should be loosely applied. Other conditions

probably brought about by the inevitable conditions of military life are trench fever, which it is believed is transmitted by the bite of infected lice, aided by cold, wet, and fatigue; trench nephritis; tetanus—a prophylactic subcutaneous injection of 500 United States Army units of tetanus antitoxin contained in about 3 c.c. of horse serum is given at the earliest possible moment in every case of wounds, however slight, and in severe cases a second dose of the same strength is given on arrival at the base hospital. Another complication of wounds is infection due to the *Bacillus aerogenes capsulatus* of Welch (*B. perfringens*), in which the prophylactic treatment depends on loose bandaging of the lino, frequent changing of dressings, sufficient drainage of the wound, and the introduction of an antitoxin. In regard to venereal disease, Burt adds that the ruling that punishment will be awarded in all cases upon proof that the disease exists, has done much to stamp out this enemy.

6. The Intraarterial (Vertebral) Administration of Tetanus Antitoxin.—Robert B. Pratt submits a discussion of tetanus and the methods of treatment at present in use. He states that the intracerebral and subarachnoid methods of administration of antitoxin deserve no consideration and, quoting from Keen's Surgery, that the inability of the nervous tissue to take up antitoxin from the circulation shows the futility of subarachnoid injections and reminds us that subcutaneous and intravenous injections are only of value in so far as they neutralize toxin circulating in the blood, but cannot influence the process in the spinal cord, and that the only rational method of administration is by intraneural and intraspinal injections. He says further, the statement that nerve tissue is unable to take up antitoxin is an unproved deduction from what follows our present mode of injection and the answer seems rather to be that we do not get sufficient quantity in contact with the toxin laden anterior cornual cells because either we fail to give sufficiently tremendous doses subcutaneously and intravenously to overcome wastage or we do not give fairly large doses in such a manner that the antitoxin will be brought rapidly and unchanged and only slightly diluted to the relief of these cells. The tendency during the war shows an imperfect recognition of these facts with consequent increase in dosage and with probably some lowering of mortality, which, however, is pitifully high. Pratt considers Roger's method of injection directly into the cord to be fundamentally correct and an attempt at something that can probably be accomplished on a larger scale in another physiological way. He proposes the following method of intraarterial (vertebral) administration of tetanus antitoxin: Prophylaxis according to accepted standards; removal of the source of supply of toxin by the excision of tissue at the site of injury and the flow of any remaining toxin blocked by intraneural injection; (intracaudal injections are uncertain as it is difficult to inject into nerve trunks); neutralization of the toxin in the blood by large subcutaneous or intravenous injections repeated daily or oftener. In order to neutralize the toxin in the motor cells of the cord and medulla, the author suggests that a large dose or doses be given directly into one or both vertebral arteries by puncture of this vessel, during exposure under general anesthesia, as soon as a diagnosis can be made. The rea-

sons for this method are: (1) Proteins—toxins, alkaloids—when injected intraarterially, become fixed in the cells in the capillary distribution of the artery employed. (2) The vertebral arteries furnish a large proportion of the blood to the spinal cord and medulla through the long descending anterior and posterior spinal arteries which are given off near the medulla; the remaining blood supply comes from very small cervical branches of the vertebral and spinal branches of intercostal, lumbar, and sacral vessels. While there is free anastomosis throughout the circle of Willis, it is yet a fact that cocaine injected into the common carotid produces anesthesia of head and neck without medullary involvement, which would lead us to believe that there is a fairly sharp demarcation between vertebral and carotid distribution. As tetanus involves practically only the cord and medulla, the arterial blood of the vertebral will reach directly the attacked cells. Material injected into one vertebral reaches the entire distribution of both. Pratt recommends that under general anesthesia the vertebral artery be exposed as follows: Make a curved incision over the angle formed by the posterior border of the sternomastoid muscle and clavicle, and retract the muscle inward; it is often necessary to cut a few of the outer clavicular fibers of the sternomastoid. Incise the deep fascia; locate the carotid tubercle; displace inward the jugular vein; define the space between the inner border of the scalenus anticus and longes coli, and find the vertebral artery by its pulsation. The vertebral vein lies directly in front of it. Then pass the fine, slightly curved needle of the loaded syringe into the vessel upward and inject a relatively large dose of antitoxin slowly. Any oozing may be controlled by packing the wound. Should subsequent injections be indicated and it be impossible to give them into this artery, the opposite one should be exposed. Pratt points out that the method is no more difficult than trephining and injecting into the brain and is justified by the present hopelessness of the great majority of cases. It fulfills the theoretical pathologic physiological requirements of reaching the heretofore inaccessible toxin in the cord and medulla, and should be as safe as any other of the methods in vogue. The method was first applied by Major Charles F. Nassau, M.R.C., at the Frankford Hospital, Philadelphia, in February, 1918.

3. Morbid Impulses.—Alfred Gordon points out the importance of the study of morbid impulses from the social and medicolegal standpoint. He shows that morbid impulses constitute episodic manifestations in the life of neuropathic individuals, that in the latter the most important characteristics are found in their psychological sphere, and that the best illustration of loss of psychical equilibrium is found in obsessions and morbid impulses, the latter the consequence of the first. He gives the characteristic feature of an obsession as, (1) lucidity as to the phenomenon; (2) energetic struggle against the invaded thought; and (3) moral torture. The elements of morbid impulses are, (1) sudden function of a center or of a group of isolated centers without participation of reason; (2) momentary impotence of will controlling the act. Obsessions and morbid impulses may develop in a neuropath who becomes fatigued, whose nervous system becomes exhausted. Depressive emotion, prolonged effort of any kind, excess of any sort, abundant hemorrhages, disturbance of

nutrition, intoxication (especially alcoholic), sight of capital punishment, recital of a murder, or news of suicide or homicide may all be provoking causes of morbid impulses, and the author illustrates this by an account of two cases. Such obsessions and impulses may also cause kleptomania, arson, assault, sexual perversion. The symptoms may be periodic and intermittent; they may be stationary for months or years; or they may disappear and recur from the least cause. Although morbid impulses for minor offenses are frequent in neuropathic individuals, irresistible impulses towards acts of graver nature are not frequent, and this should be borne in mind in making a diagnosis. Gordon points out that when a lunatic assassinates, he is under the control of a delusional conception; by which he is carried away toward the abnormal impulse. The latter has a special character, viz., unconsciousness of the act; automatism is the essential feature. In a neuropathic individual, on the other hand, the characteristic features of the act are lucidity of consciousness, mental torment, and realization of the horror of the act. The patient is in a state of anxiety, which is accompanied by cardiac palpitation, pulse acceleration, headache, tremor, perspiration, etc. In considering the question of responsibility of individuals presenting morbid impulses, Gordon points out that in primitive society punishment was always meted out, irrespective of any other consideration. The Romans were the first to distinguish between *compos* and *non compos mentis*. Pinel succeeded in convincing human minds that insanity was a disease. The new anthropological school arose and the criminal came to be considered as not fully responsible for his acts. Yet, notwithstanding the work of the psychiatrist and the student of psychology some jurists are still loath to accept the humane and scientific principles laid down by these workers. Jurists, alienists, and anthropologists differ as to the degree of responsibility of degenerates with morbid impulses during their lucid intervals. Gordon concludes with the following propositions: (a) The legal conception of responsibility is not in accordance with the principles of science and does not satisfy the practical exigencies of life. An alienist should be called upon to examine such a criminal. Administration of justice in such cases should be confided to a jurist and to an alienist. (b) Administration of houses of correction should be placed in the hands of alienists and pedagogues. (c) Youthful criminals should be placed, not in prisons, but in special institutions where they shall receive medical attention. (d) Conviction of criminals intellectually and morally defective is unjust and should be replaced by prophylactic measures which form a part of social hygiene.

3. The Relation of Blood Pressure to Convulsions.—D. M. Ervin has reached the conclusion from detailed observations on four patients that a convulsion in all probability is precipitated when the blood pressure becomes lower than the intercranial pressure, and that measures taken to raise the peripheral pressure will stop a convulsion since the blood pressure is a function of the intercranial pressure. He points out that it logically follows that measures must be taken to reduce the intercranial pressure in order to accomplish any

permanent relief. He also points out that the fact that a convulsion stops is an argument in itself against the belief that a chemical substance reaches such a concentration as directly to produce the convulsion.

2. Army Nephritis.—Captain C. F. Coombs gives an account of 160 cases of nephritis which came under his personal observation in a base hospital in France during the period from January to July, 1917. He found the chief disposing factor to be the age of the patient, five-eighths of his patients being over thirty; the season appeared to make little difference. Of the whole series only six cases were officers. In sixteen cases there was a history of previous renal disease; in twelve of scarlet fever; and in five of diphtheria. Direct bacterial investigation was not made, but, arguing by the inferential method, Coombs has reached the conclusion that army nephritis is of infective origin, since the first stages of the disease are often marked by fever and frequently associated with influenza, bronchitis, trench fever, gastroenteritis, boils, tonsillitis, or other infective condition. In addition, there are symptoms of irritation of the urinary tract similar to those caused by the *B. coli communis* in infection of the renal pelvis and bladder; and the condition is very similar to scarlatinal nephritis. The author, however, does not believe that the disease can be ascribed to any special agent, and the absence of the epidemiology would seem to negative the assumption that it may be due to an infective agent as yet undiscovered. He explains its greater incidence in the army as compared with civil life by (a) sensitiveness of the renal tissues due to fatigue and exposure, (b) greater liability to the entrance of infective agents into the blood stream and thence into the kidneys. In short he regards the disease as provoked by the passage of microorganisms or their toxins, through the systemic circulation into a kidney that has been "sensitized" by the trying conditions of military service, especially in men of over thirty years of age. Army nephritis is characterized by, insidious onset, urinary irritation with hematuria in some cases, constipation, slow pulse, appetite good as a rule, fever, headache, dyspnea, and edema. Cardiac physical signs show certain alterations; the beat, which is slow and firm, is not displaced as a rule; it is the auscultatory signs that are altered. Coombs found that the diastolic interval was shortened in about 50 per cent. of cases, and the worse the case the more definite the shortening. More frequent still was a ringing accentuated second sound heard with greatest distinctness at or near the apex. Pulmonary physical signs may be bronchial or basal. Abdominal signs are not important. The output of urine is low at first but begins to rise on the third day, over 100 ounces being passed in some cases on the fourth or fifth day. In the present series, albumin was found in the urine in 153 cases, blood in 106 cases, and casts in 104. Twelve cases manifested uremic symptoms, four of which died; two of these deaths were, however, due to concurrent bronchitis. Death occurred in one out of eight cases which had convulsions. It was noted that uremia developed when the oliguria present on admission in severe cases had been replaced by an adequate output of urine. As a means of diag-

nosis, Coombs recommends the salicyl-sulphonic acid test. The mortality in this series was 3.75 per cent. The author points out that the most dangerous type of army nephritis is that in which intense nephritis occurs in conjunction with severe bronchitis. Next to these cases come those with intensely severe and ingravescent urinary changes associated with uremic symptoms, of which the most significant is free and persistent hematuria. A third danger to life lies in possible cardiac failure. The ultimate prognosis cannot yet be stated, but there is great likelihood of relapse. Early diagnosis is the first essential in treatment. The diet should be light at first but fish, potatoes, etc., should be allowed as soon as the symptoms begin to improve. (Coombs believes that a more generous diet might have stood off the fatal issue in one of his cases.) Hot air baths are indicated when edema is present. Coombs found drugs as a routine measure unnecessary. Caffeine was of no use; tartrate of potash was of possible value, but he adds the patients might have done as well without it. In the treatment of cases with bronchitis, the free administration of atropine sulphate may be of use; in one of the author's cases it apparently saved the man's life. Lumbar puncture was tried in two cases of uremia but did no good. The best line of treatment seemed to be venesection, with sedatives if fits were troublesome. Chloral and bromide, one dram of each, given per rectum, sufficed in several cases; chloroform was necessary in one instance. Venesection was also of benefit in cases of threatened cardiac failure, and in two cases it was followed by hypodermic injection of strophanthin in full doses—a treatment which apparently saved the life of both patients.

February 11, 1918.

Laparotomy During Pregnancy.—W. Nagel gives the details of four laparotomies performed during pregnancy, three of which did not interrupt gestation. In the fourth case the fetus died two months after the interference, but a paternal syphilis seemed more probably the cause of death. Two cases were ovarian tumors, one a subserous fibroid and one a pyosalpinx. The writer discusses the threadworn subject of the indications of ovariectomy during gestation and concludes that all tumors should be removed at the beginning of pregnancy and if discovered later on the operation should be deferred until the fetus is viable. He states that the abdominal route is preferable, and such a remark made in the year 1918 can only make one wonder at the "kultur" of the author. He also points out that double ovariectomy is not more serious than when the lesion is on one side only, a fact well known, at least in most countries, for a number of years. As to myomata, they can often be removed without causing interruption of gestation, and the writer opines to their removal when of the subserous variety and seated low down in the pelvis so that they would interfere with delivery, or when on account of a long pedicle they can drop into the small pelvis. The same applies to peritonitis occurring in the neighborhood of the fibroid.

Treatment of Tuberculous Peritonitis.—O. Heinemann refers to the favorable effect of laparotomy in tuberculous peritonitis, which has been known since the days of Sir Spencer Wells, and very correctly states that the mechanism is to him still obscure. The case which Heinemann reports offered a certain general reaction following the operation in the form of a bilateral pleural collection and ascitis. Strange to relate, repeated puncture did not arrest the onward progress of the process, but the laparotomy allowed the distinguished clinician to verify the tuberculous nature of the ascitis (tubercles on the peritoneum and intestine) and resulted in a "satisfactory" cure in a few months with disappearance of the exudates and an increase of 16 pounds in weight. If our memory fails us not, we believe we have heard similar results at the hands of other operators.

Münchener medizinische Wochenschrift.

February 12, 1918.

The Effect of Neosalvarsan on Malaria.—L. Mandoki and W. Maule state that Coci's method consists in the

provocation of blood parasitosis resulting from the exhibition of small doses of quinine. A daily dose of 5 centigrams of the hydrochlorates produces a paroxysm or at all events the entrance of the specific organism into the blood stream. The writers have been able to detect latent malaria in 50 per cent. of the cases thus treated. In 60 cases in which a negative result was obtained only 7 gave a positive reaction by other methods. On the other hand, Coci's method, which is very recommendable on account of its simplicity, will result in positive findings in cases where other provocative methods have failed. The test necessitates the exhibition of the quinine for four weeks. A mixed treatment should follow this test, namely, with quinine and neosalvarsan. Although the latter drug may not sterilize the patient, the paroxysm is delayed for from eleven to twenty-two days from the time of the injection, which represents the necessary lapse of time for the development of the generations of the organism sufficient to produce an attack. Neosalvarsan kills the asexual forms of the organism, but it seriously affects only the gametes of the tertian type, while on the tropical forms of the disease it seems to exert not only no lethal but even an irritating action. Likewise it appears that this is also the case for the quartan type.

Myositis Following Influenza.—H. Burger has observed three instances. The duration of the myositis was six weeks or more and manifested itself by pain in the muscular groups involved, spasms and rise in temperature. Recovery was complete and left no sequelae. In all three cases there was a lymphocytosis of about 40 per cent. This complication of influenza is probably more common than is generally supposed and Burger says it should be treated very energetically with aspirin, quinine, and novatophan. The parts shall also be treated locally with applications of ichthyol and aluminum acetate.

Deutsche medizinische Wochenschrift.

February 14, 1918.

The Treatment of Tuberculosis with Partial Antigens According to Deycke-Much's Method.—Kwasek and Tancre have experimented this procedure in out-patient practice on 47 cases of pulmonary tuberculosis, 4 cases of urogenital tuberculosis and 1 case of tuberculous lymph-nodes. With an average of six months' treatment in each case, the following results were obtained: 4 cures, in 2 of which the bacillus of tuberculosis disappeared completely; 10 cases in which the fever subsided; increase of weight in 9 patients; in 11 pulmonary and in the 4 genitourinary cases no result was obtained and, lastly, 24 patients were made worse by the treatment. The writers attribute these rather disastrous results, as compared to those more favorable ones obtained by other writers, to the gravity of the cases they subjected to this treatment.

The Bacteriology of Gas Edema.—L. Aschoff again affirms that between malignant edema and gas phlegmon there are many intermediary varieties. He recalls the difficulty of morphologically differentiating the various bacteria of gas edema. The ties existing between the bacilli of malignant edema and symptomatic anthrax are very vague. The question of the transformation from one form into another of the various types of bacteria of malignant edema cannot be denied by a mere negation as Fraenkel has done. Taking as a basis 2,356 cases treated with anti-gas edema serum, Aschoff estimates that the use of this serum reduces the mortality from 68.7 to 43.9 per cent. If these percentages are confirmed by future essays, it will mean the saving of life to the extent of 25 per cent. in cases of gas edema.

Milk Treatment.—H. Reiter is of the opinion that the results of treatment by subcutaneous injections of milk are as yet most uncertain. The procedure is not based on any really serious experimental work and the results obtained by various writers are contradictory. Lastly, this treatment may be nefarious, in as much as it excludes well-tried and efficacious methods from being resorted to.

Wiener medizinische Wochenschrift.

March 2, 1918

The Pathogenesis of the Pemphigus Bulla.—F. Samberger in this article, continued from the previous issue, states that adrenalin exercises a favorable action on acute attacks of vagotonic pemphigus but has no effect on the disease *per se*. This also applies to urticaria. Basing his remarks on the fact that the bullæ of pemphigus are bordered by erythematous spots, Samberger combats the theory of pemphigus from vascular paralysis and maintains that the primary cause of the bullæ is vasoconstriction. Besides vasoconstriction other factors may cause the formation of bullæ in pemphigus, and as proof of this the writer refers to three cases observed by Prokop in men dying from submersion in fine sand.

The Physicochemical Peculiarities of Weil-Felix Proteus X 19.—H. Mautner recalls the fact that nearly all bacteria can be precipitated by chemical or physical agents. He has observed that the concentrations of methylic or ethylic alcohol which are without effect on control bacilli, rapidly agglutinate the proteus vulgaris and still more rapidly the Weil-Felix organism. The writer questions whether these findings cannot find their explanation in the reaction of typhus fever. The serum in this case acquires agglutinating properties as far as the most labile bacteria are concerned. This agglutination should likewise be considered as non-specific. Agglutination by alcohol offers, like specific agglutination, the property of removing this faculty from the agglutinating liquid, once the reaction has commenced and centrifugation has been done.

11. Death of Dr. Flavel B. Tiffany. F. M. Fernandez.

1. Successful Method of Extraction of Congenital and Traumatic Cataracts.—J. Santos Fernandez gives his results in these cases; he is in favor of the needling operation and condemns the simple extraction method as liable to cause the loss of the eye. The dissection of the opaque lens can be repeated as many times as necessary, but the author has not had to do so more than twice, or in some very stubborn cases three times.

2. Reflex Amyotrophies of Articular Origin.—Julio Ortiz Cano declares that in every case of traumatism involving the large joints, the surgeon should advise the patient as to the possible occurrence of muscular atrophies and resulting functional loss. All the joint lesions either due to traumatism or spontaneous, cause a reflex action upon the corresponding trophic or motor center, which reflex action has been well described by Cajal. The author gives the histories of nine cases in which only the extensor groups of muscles were affected and the electric reaction shows that the atrophy was simple, as the reaction of degeneration was not present in any case. Treatment should be directed to rest the injured joint.

Il Policlinico.

February 10, 1918

Causalgia and Its Surgical Treatment.—Tenani writes at length on this subject. Burning pain in a definite nervous distribution is a symptom which has been mentioned off and on in medical literature but was first described by Weir-Mitchell in 1864 in connection with injuries to the nerves. In the course of the present war the subject has assumed new importance. The

affection is certainly rare and refractory to treatment, so that recourse to surgery is suggested and actually has been had in cases of causalgia of the arms and legs. Weir-Mitchell decided that causalgia was due to an ascending neuritis, but more recent studies seek to accuse the sensory and trophic nerves and blood vessels. The characteristic hyperesthetic zone transcends the boundaries of analgesic and paresthetic zones present when the given nerve trunk is compressed. The sensory component is a painful hyperesthesia. The claim has been made that osseous alterations may appear. Causalgia is not limited to the lower extremity, but may affect the hand and arm. As a matter of fact, studies have been made of causalgia due to lesions of all the large nerve trunks and apparently cases occur after lesions of vascular trunks. The painful parts feel as if on fire and there is no relief save from cold applications. In fact, in certain cases the hands or feet have to be kept constantly refrigerated. A latent interval of considerable length usually occurs between the date of the trauma and that of the first symptoms of causalgia. Considerable individual variation is seen in the different nerve areas—the median area is apt to be the seat of pain and trophic change, the radial of paralysis, the cubital of contractures, etc., etc. Meige and Benisty once studied the results of associated injuries of nerve and vascular trunks and found that a great number of symptoms were variously associated. According to the nature of the injuries of both trunks there could originate such dissimilar conditions as causalgia, Volkmann's syndrome, and Reynaud's disease. Later these authors saw in causalgia a neuritis of the sympathetic, having decided that vascular lesions could not give rise to this picture. In any wounds of the artery its sheath must be wounded, and in this sheath occur most of the fibers of the regional sympathetic. Leriche proposed to cure causalgia by simply excising its sheath from the artery. In August, 1916, he performed this operation on the brachial artery for causalgia of the arm and the patient recovered rapidly. During 1917 he saw a case of causalgia of the arm secondary to a resection of the clavicle with freeing of cicatricial tissue, done for a war wound. Although the seat of the lesion was much higher, he dissected off the sheath of the brachial artery to the extent of 12 cm. and cured the case. The vessel no longer pulsed and was shriveled. The various sensory vasomotor and trophic disturbances, however, promptly receded. The limb had been paralyzed since the injury but there was some return of motor power in the forearm. The author has also had two operative cases of causalgia, both in the lower extremity. The first patient had severe pain in the left foot, which he was forced to keep in ice water. The wound was in the middle of the thigh and seven days elapsed before the appearance of the causalgia. The muscles of the limb began to atrophy and there was marked hyperesthesia. The x-ray showed no skeletal alterations. The author cut down to the femoral artery near the injury and excised 12 cm. of its sheath. The artery and vein were normal. A mass of scar tissue was extirpated. There was immediate relief followed by complete restoration. The second case, which was somewhat similar to the first, was cured in the same manner. Necessarily this operation, which is a special type of sympathectomy, did not originate in connection with causalgia, for Jaboulay had originated and perfected it by 1899 in the treatment of perforating ulcer of the foot and other ailments.

Othematoma in Prisoners.—Doctor Pierre-Louis Marie, who spent 10 months in a prison camp at Zossen, saw many cases of othematoma, a condition sometimes cumulative in insane asylums. The collectivity in this camp was 15 cases per thousand prisoners. The cause was doubtless anemia from privations of all kinds. The prisoners were French and Belgian soldiers interned over 8 months. Other affections due to privation were hemeralopia (this seemed to be limited to Russians), eruptions, edema, nephritis and ordinary scorbutus. The diet consisted chiefly of cereals and dried legumes. Fresh meat, fresh vegetables and fruits were never on the menu. In othematoma violence could be excluded. The condition could be regarded only in the light of a localized scorbutus.—*Archives de Médecine Militaire*.

Book Reviews.

PROBLEMS OF MYSTICISM AND ITS SYMBOLISM. By Dr. HERBERT SILBERER of Vienna. Translated by SMITH ELY JELLIFFE, M.D., Ph.D. Price, \$3.00 net. New York: Moffat Yard & Co., 1917.

IN this book Drs. Jelliffe, Lay, and Stein have rendered accessible to the English-reading public the researches of Prof. Silberer into the subject of mysticism. An ancient parable, dating very probably back to the sixteenth century, is quoted entire and then analyzed by the psychoanalytic method. From this the author goes on to show the universal wish-fulfilling motive lying behind all the varieties of mysticism, hermeticism, alchemy, and the like. The connection is then shown between symbolism as the expression of a race or group and introversion as an individual reaction. The whole work is fashioned from a wealth of material and shows the pre-eminently Teutonic faculty of infinite pains. As an interesting example of the thoroughness with which the psychoanalytic school has extended its doctrines to embrace many departments of knowledge this book is well worthy of consideration; as a solid contribution to the study of psychology and psychiatry its value is less clear, and to the general practitioner, now busy beyond the imaginings of ante-bellum times, we find but little to commend it.

LES LÉSIONS DU CORPS THYROÏDE DANS LA MALADIE DE BASEDOW. Par GUSTAVE ROUSSY, Professeur Agrégé à la Faculté de Médecine de Paris. Médecin en Chef de l'Hospice de Villejuif. Price, 3 Francs. Paris: Masson & Cie., 1914.

AT the present time, when the neurologists regard the lore of the ductless glands as belonging exclusively to their province, we should not be surprised when a well known alienist writes a monograph on the subject of Graves' disease. The fact that this work has reached the market four years after date of publication is one which does not concern the reviewer. We may note in passing that this brochure of 137 pages is printed on heavy calendared paper, which may indicate its ante-bellum origin. The bibliography occupies twelve closely printed pages—nearly ten per cent. of the book. The ten text figures and seven colored plates are all microscopic representations. While the work is based on extensive first hand studies and diligent research into literature, it is very largely speculative in its general treatment.

HUMAN PHYSIOLOGY. By PROFESSOR LUIGI LUCIANI, Director of the Physiological Institute of the Royal University of Rome. Translated by FRANCES A. WELBY. With a preface by J. N. LANGLEY, F.R.S. Professor of Physiology in the University of Cambridge. In five volumes. Vol. IV. Edited by GORDON M. HOLMES, M.D. The Sense Organs. Price, \$5.25. London: Macmillan & Co., Ltd., 1914.

THE present instalment of Luciani's magnificent work will probably prove to be the most interesting volume of the whole series. It deals with the Sense Organs; and this is a part of physiology which is generally very briefly handled in the standard textbooks. These latter have, as a rule, adequate chapters on taste, smell, hearing, and vision; but they are apt to be deficient in their treatment of the internal sensations, muscular sense, the sensibility of muscles, tendons and joints, common sensation of the body (or coenesthesia), sexual desire, hunger and thirst, etc. In the first two chapters of this volume Luciani discusses these subjects thoroughly, as well as various philosophical points in connection with sensation in general. The editor has wisely added a note on Head, Rivers and Sherren's work on the mechanism of peripheral sensibility, and on protopathic and epicritic sensibility. The last chapter, on Psycho-physical Phenomena of Consciousness and Sleep, will also form attractive reading for those interested in these subjects. Not only physicians and physiologists will welcome this volume, but psychologists will find here a masterly discussion of that part of physiology which particularly interests them, and which, as a rule, they have to obtain from the general works on physiology. When this work is completed it will easily rank as the standard work on the subject in English. We have, on previous occasions, referred

to the skill with which the translation is done, and also to the value of the bibliographical references. We await the appearance of the remaining volume with interest.

TROUBLES LOCOMOTEURS CONSÉCUTIFS AUX PLAIES DE GUERRE. Par AUG. BROCA, Professeur à la Faculté de Médecine de Paris. Price, 4 Francs. Paris: Masson & Cie., 1918.

THIS volume differs from many of its fellows in being rather sparsely illustrated, there being a relatively small number of text figures and no plates. In the natural association of events one would expect to find a book of this sort well provided with pictures. The conditions described comprise chiefly ankylosis, true and spurious, cicatrices, muscular contractures and vicious union of bone. To avoid duplication of matter in the series, there is no section devoted especially to lesions of the nerves, although such are considered in connection with affections of the muscles, etc. The chief asset of the volume is the name and fame of the author.

THE ROAD TO A HEALTHY OLD AGE. By T. BODLEY SCOTT, M.R.C.S., Eng., L.R.C.P., Ed. Price, 4s. 6d. London: T. Fisher Unwin, 1917.

DR. SCOTT is an authority on how to attain to a healthy old age and how to lengthen one's life and live happily when that goal has been reached. The question of the prolongation of life, according to the author, depends largely upon the choice of food, as, in his opinion, age, with its lessened physical work and activity, needs less strong and stimulating food. The book deals with the value of foods, the prolongation of health, premature senility, and the treatment of chronic bronchitis and bronchial asthma, the two most frequent diseases of old age. He points out that during the past few years the knowledge gained of the properties of the internal glands and further knowledge of biological chemistry have enabled physicians to do much more for the prevention and cure of many of the morbid conditions of advancing years. The work is both interesting and instructive, displaying scientific knowledge and literary ability.

AN ADVENTURE IN PHILANTHROPY. New York Charity Organization Society, 1918.

"AN Adventure in Philanthropy" is a very interesting tale written with a purpose. The purpose is to emphasize the inadvisability, or rather the lack of wisdom in distributing charity indiscriminately, and shows that such a mode of endeavoring to assist those who need aid often defeats its own object.

DÉCOUVERTE DES VAISSEAUX PROFONDS PAR DES VOIES D'ACCÈS LARGES. Par J. FIOLE et J. DELMAS. Préface de M. PIERRE DUVAL. Price, 5 Francs. Paris: Masson et Cie., 1917.

IN this little manual of surgical dissections, which is said to be an outgrowth of war needs, the absence of all colors in the thirty-four plates and text figures strikes us as unusual, for the book is perfectly executed save for its temporary paper binding. While in many works which deal with operative surgery we find only uncolored illustrations, the use either of colors or explanatory figures seems indicated for a reference military manual. The subject matter is limited largely to wide exposure of the large vessels and their isolation from other structures preliminary to ligation or other vascular intervention, and the book doubtless fills a niche which has been unoccupied.

AN ACCOUNT OF THE PRINCIPAL WORKS OF THE ATREYA SCHOOL OF MEDICINE WITH THEIR CHRONOLOGY. By KAVIRA, BIRAJA, CHARAN GUPTA KAVIBHUSHANA, late Court Physician of Cooch Behar, etc. Calcutta: P. S. Gupta, 1917.

THIS little work hardly possesses any value to the American physician, for, while devoted to chronology, it does not give a solitary date or equivalent. Of many common and proper Sanskrit names, printed in English, but few are translated, and this state of affairs is aggravated by the presence of many passages in Sanskrit text, in such small type as to be almost undecipherable. It is to be hoped that some one may edit the volume in such a way that these disadvantages will disappear.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 4, 1918.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Neuropsychiatry and the Mobilization.—Dr. PEARCE BAILEY, Lieutenant-Colonel, Medical Corps, N. A., delivered this address, in which he said, in part, that while medical men had been giving their services in providing care incidental to bursts of illness which seemed inevitable when men were gathered together in large numbers, they had also been laying the foundations of what was medicine's greatest goal and greatest future, the prevention of disability and disease. They had also, by determining the future of physical and mental fitness of American youth, by recommending disposition of those who were not fit for the full ardors of war, accumulated information which must be incorporated in the creation of new social and political policies after the war. The results of the examination of a million men by the most skilled diagnosticians in the world had proved beyond chance of denial that modern medicine, quite apart from its military significance, was an indispensable factor in practical matters and that no social theory could be true or enduring which failed to pay full heed to the facts that it proved concerning humanity. On the mental and social side it could, by means of its psychological branches, indicate certain causes of national weakness and point out means of development which had long been disregarded for the reason that the attacks they made on public health and efficiency were insidious, and also because they had never been systematically studied in large numbers. It was his privilege, Dr. Bailey said, to show some of the statistics that had been gathered in relation to nervous and mental disease, but before proceeding to the main subject he spoke of the stimulations and advantages which had accrued to workers in neurological medicine. New problems had developed in neurological medicine which opened up a field of usefulness in civil life hitherto undreamed of, new symptom groups had become manifest which, while not actual disease, handicapped those who suffered from them, so that they were unable to do the work of a normal man. These symptom groups constituted a field hitherto unexplored, groups which constituted a medical "No Man's Land," lying beyond the point where a man could be said to be actually ill, and yet not reaching the point of full adult efficiency. Of the new problems, some of which might be solved before the war was over, might be mentioned bed wetting, the frequency of which in healthy adults has astonished most of the newly appointed medical officers. It might have some physical basis but also seemed like a situation neurosis and to require a special study in terms of situation. Many of the other neuroses so common among troops, doubtless, had association with the physical causes. As an example of this general class might be mentioned hyperthyroidism. These cases, called by the English "effort syndrome," consisted in the general mild toxic symptoms of hyperthyroidism, but the individuals themselves were all highly neurotic and gave a history of inability to do more than temporary work and that only with uncertainty. They had rapid hearts and showed certain functional changes in the cardio-vascular apparatus. They were midway between health and disease and it seemed as though a remedy would be found for them, possibly in surgery. Another problem which has been opened up which linked various branches of medicine, and which offered opportunity for refined diagnosis with practical ends, came from the study of the types of personality of aviators. The high percentage of the initial accidents in aviation were reducible to the fact that the aviator was not physically fit. It was not, however, an ordinary unfitness. He might have successfully passed the most rigid routine, physical examination and still be found by newly devised tests to be unsafe under certain conditions in the air. To determine beforehand these conditions and thereby to eliminate unnecessary accidents, most ingenious methods of examination had been

devised by a Medical Research Board. They had found the means of determining to what altitudes and under what special conditions a certain aviator could be safe. These tests were based on the subjects receiving diminished supplies of oxygen to correspond with the oxygen content of the atmosphere at mounting altitudes. Various tests of the attention were made until it was found at what altitude an individual would begin to waiver in his attention. The ocular apparatus was tried out, especially in the ability to perceive luminosity, power of accommodation, and power of continuous fixation. By the simple withdrawal of oxygen, and noting the sequences in which various physical or mental faculties failed under the experiment, the estimation of individual efficiency seemed to have been reduced more closely to a physical basis. It seemed that this test which was bound to increase the efficiency of the flying corps was also destined to become of great value in medicine. A new psychological method had been developed as a result of the mobilization. The old method of determining mental defect by the man's behavior was under service conditions totally inadequate, and a method of individual examination for each man was also too slow to be effective in a military way. This situation was met by a group of psychologists headed by Major Yerkes who devised psychological tests by means of which the extent of mental deficiency in large groups of men could be determined in a short period of time. These psychological examinations had been of great help to medical officers and in so far as they gave an intelligent rating to all enlisted men examined were met by the hearty approval of line officers. Line officers had found it to their advantage to follow in their assignment to duty the intellectual ratings of enlisted men as furnished to them by psychologists. These examinations had also been extended to newly appointed officers.

A great practical advantage which had accrued to the medical profession as a whole in the present mobilization had been the closer cooperation of the different branches of medicine than any hitherto known. Throughout the cantonments, hospitals of one thousand or more beds had been manned by picked groups of specialists who by reason of the association of the common inspiration had lost much of the narrowness so long characteristic of specialism. As an instance of this, it had been arranged at the group of psychological examinations which were conducted by psychologists that two or more of the neuropsychiatric group were present for assisting and expediting the work as far as concerned mental deficiency. The early recognition of nervous and mental disease and types of personalities have been shown to be of extreme importance. Many of the purely physical disabilities which were noted and waived by mustering officers, or which disqualified recruits for service, were susceptible of cure or improvement by treatment, or here and there some might get well of themselves under the favorable conditions of military training. This was rarely the case for any nervous or mental disease. Probably 80 per cent. of these men treated for these causes in the camp hospitals were discharged from the service and the longer the training period was prolonged, the more pronounced these conditions became. A weighty responsibility had rested on the neurologists and psychiatrists of the Medical Department to safeguard the United States forces being sent to Europe from being crippled by nervous casualties. It was believed that much had been accomplished by their examination in this country directed toward the exclusion from active service of those strongly predisposed to nervous and mental disease. Examinations in this country had been systematically carried out since the beginning of the present mobilization, three methods having been employed, examination by boards, examinations by surveys, and examinations only of such cases as were referred by regimental surgeons, company commanders, etc. The same steps that were taken to prevent neurotics from becoming soldiers and officers in our army would result in a smaller proportion of casualties of nervous type as compared with other armies. The same efforts to prevent them which had been inaugurated in this country would have to be continued in whatever coun-

try the troops might be sent. A psychiatrist had been assigned to every tactical division. His duty would be to keep in close touch with the nervous stability of the troops in his division. Few of the nervous collapses which occurred at the front took place without giving some warning. For a few days or longer before finally going to pieces, the officer or soldier had given signs of not being able to endure the strain much longer. It was believed that if the individual thus threatened could be relieved of active duty for a few days and given proper treatment he might be returned to the front in a more stable condition.

Dr. Bailey then presented statistics showing the incidence of the various neuropsychiatric conditions in the National Guard and National Army cantonments. Mental deficiency was shown to be far more frequent than any other neuro-psychiatric condition. Then occurred in the order mentioned, epilepsy, psychoneuroses, constitutional psychopathic states, dementia precox, those due to alcoholism, and those due to syphilis of the central nervous system. Other neuropathic conditions occurred very infrequently. In commenting on these figures, Dr. Bailey said one could not contemplate them without asking the question, "What is to be done with, or for these individuals?" The question was not one of the reconstruction of injured soldiers, but the reconstruction of our own population whose defects existed quite independently of the war. The reconstruction thus considered was under two heads: (1) Reconstruction for the purpose of military service, and (2) reconstruction to meet the ordinary requirements of civil life. It had been the original intention of the Medical Department to reconstruct for the military service all those who could be reconstructed in a reasonable length of time, but the constant changes which were going on in this war made changes in this policy inevitable on short notice. It would, doubtless, do so ultimately, but could not promise to do it now. At the same time it was possible for the civil authorities to take over that part of the burden and to organize their activities that men rejected from the Army could be provided for in some way by their states pending such time as the Federal Government would be able to supervise the whole program. This action should come just now at the initiation of the states themselves and it was a very encouraging sign that one state, Arkansas, had already done this. It was to be hoped that the example of Arkansas would be followed by other states.

In concluding, Dr. Bailey expressed certain views reached as a result of the examinations being made of our young men. These, he said, looked toward the necessity of the reconstruction of our national policies as the result of this war to insure a high standard of national health. The conception of individual liberty would have to be changed in so far as it concerned individuals who were not physically or mentally entitled to the exercise of full liberty. Our laws, as they existed today, were extremely inadequate in providing control for mental defect which had been shown by the tables presented to be such a frequent disability. The laws would have to be made much more stringent to provide for the custodial care of mental defectives and to prevent absolutely the propagation of this distinctly hereditary condition. Furthermore, it would be imperative for the Government, after this, to have accurate knowledge of the health of the people. The examinations which had been made in the camps would have to become a part of our annual national program and there seemed no other way of providing for this except by universal military training. Young men would have to report for certain periods in their youth not only to be examined but to be tried out for a few months to test their physical and mental preparedness and endurance. The advantages of such an enforced service were not only physical, but would affect also the mental health and happiness of the whole people. No one could doubt this who had witnessed the individual members of the first draft coming to camp and who again saw them a few months later, trained as soldiers. For the creation of national feeling, community of life and purpose, the environment of military service seemed imperative. The general reconstructive program of

the country would have to be carried out by some agency which, while not interfering too much with individual states, would still be able to influence them to the adoption of a common health problem. The Federal Government must be put in possession of facts concerning its birth rate, its death rate, and the diseases in different localities; it must further have power so to influence individual states to take care of these problems that the result might be favorable to the nation as a whole. In our public Health Service we had the beginning of this, but its powers and functions must be greatly enlarged in order to obtain the end in view. Physicians must mix more in political and civic affairs and relinquish more than they had ever done their predilection for study and take on actual public service in the application of the principles of their art. Finally, Dr. Bailey made a plea for more physicians for the service, younger officers to take the places in the cantonments of those who were going with the Expeditionary Forces, and older men who, as instructors, would give of their ripe professional experience, and who would assist in the solution of the many new medical problems the war had brought to light.

Dr. CHARLES L. DANA, after expressing his appreciation of Colonel Bailey's interesting and stimulating address, said he wished very much that the address could be given before other audiences in other places. There was no doubt that such a vivid presentation of the Government's work would be most effective in arousing patriotic interest. Dr. Bailey had covered his subject so completely that the speaker wished simply to emphasize one phase of the problem which had been presented. The Surgeon General's office, and particularly that division over which Colonel Bailey presided, was very much in need of experienced medical men, and the question was to get more such men from civil life without crippling the activities at home. The doctors in New York City, aside from their regular practice, were working in colleges, hospitals, and dispensaries, in the Health Department, and in laboratories. Now there were five colleges in the city, with five sets of professors teaching the same branch. Was it not possible for these to combine so that one man or possibly two men could do the work instead of five? The problem was difficult, but it could be worked out if it had to be done. For instance, in regard to the hospital workers, there were 184 hospitals in Greater New York and the speaker would suggest that the hospital men might combine, so that one man could do special work in several hospitals and release the others, or the staffs could be enlarged by calling the consultants to active service again. There were over seventy general dispensaries in the city. A plan had already been suggested and successfully carried out in Boston of calling in some of the older men who were partly retired practitioners to assist in the work of the dispensaries. Besides this, nurses or special aides to nurses could assist in history taking and social work. Dr. Dana expressed the belief that a good deal of the health work could be done by trained men and women who were not physicians, and the same was true of work in the laboratories; women could be taught to become trained technicians, and thus could do work that would set free trained medical men. It was well known that after all that great obstacle which prevented many desirable medical men from joining the Army was an economic situation. A man with no financial resources, with a wife and children, felt that he could not enter a service in which he might be kept for years. This difficulty might be relieved in part by the men who were staying at home making regular contributions to assist the families of physicians who were at the front. There were many men who would be glad to contribute moderate sums monthly. Another possibility to be considered was that of utilizing men on long contracts and with definite rank. The plan suggested by Colonel Bailey for the organization of a Federal Health Service had for a long time received the approval and support of the Academy of Medicine and it was hoped that one of the outcomes of the war would be the organization of such a Federal service.

Dr. L. PIERCE CLARK congratulated Dr. Bailey on having said all there was to say on this general subject, and upon having indicated what rôle the work on

nervous and mental diseases should play in this whole scheme. There was an impression that army life produced and brought about epilepsy, yet it was generally accepted that the army was not instrumental in producing mental deficiency and that the men who were found to be mentally deficient had their defect before enlistment. The same was true of epilepsy. It might be possible that the excitement incident to a man's entering the army and adapting himself to the new conditions precipitated attacks, but the epilepsy had not been essentially produced by the army training and discipline. It was very obvious that feeble-mindedness, epilepsy, and ordinary nervous diseases should be excluded by the Boards of Examiners, and it therefore seemed essential that the men who undertook this work should be acquainted with the symptoms and detection of these disorders. He was interested to know that the neurologists and psychiatrists working in the camps had outlined a practical scheme for discovering the means of differentiating these conditions, and that such a rapid scheme had been evolved for sifting out the mental defectives. In emphasizing the fact that epileptics were not made by the army training, but that these individuals were potential epileptics before their enlistment, Dr. Clark expressed the opinion that many cases of epilepsy of this type might be restored by proper treatment. It was to be regretted that these men could not be screened out at the first examining boards. It had been found in many instances that even men known to be epileptic had been called up repeatedly for examination. A man with the type of epilepsy which manifested itself in very infrequent convulsions might easily be passed by an examining board, and it was a notable fact that these epileptics were likely to be very patriotic and anxious to enter the army. In this respect they were entirely different from the psychoneurotics, who were more apt to lack a desire for army service. It would be a great help if more pains were taken to sift out these epileptics before they reached the camps.

Dr. CHARLES W. PILGRIM, after expressing his deep appreciation of Dr. Bailey's paper, spoke of the relation of the problem of nervous and mental diseases in the army to the same problem in civil life. He said that for forty-four months preceding the war there were 27,311 inmates in the State hospitals, while during the forty-four months since the declaration of war there had been 33,000 patients in these hospitals. The increase in the number of inmates was largely in the dementia precox and manic-depressive insanity groups. A study of the situation led one to believe that the war was the reason of this increase. The recurrent cases and the readmissions also showed an increase. There were many cases in old people who had delusions, such as that the world was coming to an end, and these seemed to be traceable to the conditions brought about by the war. Again many people had gone into new employments and had been compelled to make readjustment of their lives, and many of them led very unnatural lives because of the conditions imposed by the war. The hospitals for the insane had been trying to do their share of war work. In England the hospitals for the insane had turned over 15,000 beds to the War Department. This had been done by dividing England and Wales into twelve departments and reorganizing and co-ordinating their work. They were not able to do that in this country, but they had on their service flag 331 stars, including medical officers, nurses, and other employees. The doctors, nurses, and other employees had purchased over half a million dollars' worth of Liberty bonds and they had made no fewer than 75,000 articles of clothing for the soldiers. They now expected to turn over 1000 beds on Ward's Island to the Government, so that while they were not doing what England had done, they were still doing what they could to make the world safe for themselves and for their children.

War and Childbirth.—Richter states that in Lower Austria the birth rate has been decreased by one-third in three years; boys are not more numerous than girls; the infant's weight is unaffected by the mother's privations. Eclampsia, so far from falling off, has never been as frequent.—*Zentralblatt für Gynäkologie*.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Annual Meeting Held March 29 and 30, 1918.

JOHN A. KOLMER, M.D., OF PHILADELPHIA, PRESIDENT.

The Role of Immunity in the Conduct of the Present War.—Dr. JOHN A. KOLMER of Philadelphia delivered the presidential address. He said that when the history of the present war is written, a notable victory over the common enemy, disease, will be recorded as one of the greatest triumphs of this immense conflict. This conquest of disease was probably the underlying explanation of the stamina and sustained man-power of the warring nations. Never before had so many combatants been engaged, and never had there been such freedom from disease both among the soldiers and the civil population. History records cessation of many wars, due to pestilence, but this had not had any influence in the present conflict. This freedom from disease was partly due to preventive sanitary measures, and partly to specific prophylactic immunization against various infections. The science of micro-parasitology and specific immunization could share equal honors with sanitation and the resistance of the individual to disease by proper hygiene. It could be said that without the initial step in immunization, that against smallpox, it would be impossible to maintain in health large armies and millions of the civil population. The prevention of typhoid and paratyphoid, though not so successful as smallpox vaccination, had largely reduced the prevalence of these diseases; and some check had been placed upon bubonic plague, bacillary dysentery, cholera, and rabies by active immunization. Diphtheria antitoxin treatment was a valuable measure, as was also treatment with tetanus antitoxin, especially when, as nowadays, the trench method of warfare caused wide dissemination of the virus, and practically every wound was an infected one. Epidemic cerebrospinal meningitis was now treated by potent antiserum. Even pneumonia, "The Captain of the Men of Death," was proving amenable to serological treatment. The treatment of syphilis, "The Third Great Plague" (a disease to which persons of all ages and both sexes were vulnerable), had received important aid by means of dioxyminoarsenobenzol, the chemotherapy of which was an important branch of immunization. This treatment gave hope that the disease might be curbed in the present and prevented in the future generations of mankind. Many practical problems lay before the immunologist. One was the discovery of a practical test, analogous to the Schick test, to ascertain the presence of a natural immunity to pneumonia and meningococcus meningitis (if such immunity exists). This might also obtain in the case of tetanus. Measles, anterior poliomyelitis, syphilis, and gonorrhea were diseases that must be combated by some means of active immunization, not forgetting that problem of problems, the question of immunization against tuberculosis. In the present crisis many members of the Association had offered their services to the government; all were directly working upon problems bearing upon the health and protection of armies abroad and camps at home. Viewing the accomplishments of the science of immunity, one would wish Godspeed to these workers in their toil for the present and future, for the health and happiness of mankind, for all time and everywhere.

Experiments on the Production of Antipoliomyelitic Serum in Rabbits.—Dr. E. T. TSEN of Columbia University, N. Y., presented this work. Experiments along this line, he said, were few and the results obtained thereby were contradictory. Various workers had arrived at different conclusions. The problem was, therefore, reexamined. Experiments were carried out on rabbits, and the attempt was made to neutralize poliomyelitis virus by the serum of animals injected with repeated doses of the virus. Control mixtures were prepared and used at the same time. The mixtures were tested on monkeys by intracerebral injections of 0.5 or 0.8 c.c. The result of the first experiment showed that paralysis and death were delayed in the monkey, although death finally occurred from effect of poliomyelitis virus. Experiment two was conducted on five monkeys and it was found that the antipoliomyelitic serum had no effect in delaying par-

alysis or death. These experiments may seem somewhat contradictory, but the discrepancy was slight in the results. It might be explained by differences of resistance in the monkeys. In conclusion it could be said that there was no protective effect in the serum from rabbits which had been injected with the poliomyelitis virus.

Active Immunity in Experimental Poliomyelitis.—Dr. H. L. ABRAHAMSON read this paper. This study, he said, began in 1909, when monkeys were first inoculated with the disease in the experiments of Landsteiner and Popper. Flexner and Lewis, in 1910, succeeded in immunizing monkeys by subcutaneous injections of suspension of the virus. The experiments of Roemer and Joseph who attempted to immunize by intracerebral injection of virus mixed with neutralizing serum were open to criticism. Monkeys thus treated could be reinfected. It could be said that conditions necessary for artificial immunization were: (1) That the method should protect against any reasonable exposure to the disease. (2) That the inoculation itself should be harmless. (3) That the method should not be too cumbersome or slow to be of practical value. In the experiments conducted by Dr. Abrahamson these points were borne in mind. Rabbits were found to be unsatisfactory experimental material and young Rhesus monkeys were chosen for the work. An attenuation of the poliomyelitis virus was aimed at, bearing in mind the analogy to the rabies virus. The virus was exposed (1) to heat, (2) to chemical action. In the latter modification, 0.5% formaldehyde was used. The monkeys sickened and died of what was termed "marantic" type of monkey paralysis. Modification by heat was then used, two methods of vaccine injection being tried. The first one consists of four successive daily injections of 5 c.c. of 10% emulsion in saline of brains and cords of recently infected monkeys. On the fifth day the animals received 5 c.c. of virus emulsion, unmodified by heat. The second type of vaccine was a 5 c.c. injection, on ten successive days of emulsion in saline of brains and cords of infected monkeys, heated to 55 C. for a half hour. This was really a killed virus. It was then sought to determine the amount of immunity possessed by the animals, and also the neutralizing properties of their blood serum. A number of well-controlled experiments on monkeys were carried out according to these methods and in all 11 monkeys were subjected to the 5-day injection series, without ill effect. This method, being short, would make it particularly applicable during an epidemic. It would seem to confer a strong degree of immunity. Persons having recovered from poliomyelitis contain in their blood neutralizing substances, and the same could be said of monkeys. These substances could be artificially produced, and in sufficient quantity to overcome infection of human poliomyelitis, which was far less virulent than the experimental disease.

Dr. A. F. COCA of New York said that he felt it important to emphasize the concluding remarks of Dr. Abrahamson. The conditions under which he was working to produce immunity were highly artificial and this defence was more than was necessary to constitute an absolute resistance to the natural infection as occurring in human beings. The natural resistance might need very much less than the artificial one. In the artificial experiments resistance was circumvented. The experimental resistance in guinea-pigs after immunization with toxin and antitoxin was not comparable with the successful active immunization of children against diphtheria. It would be hard to see from the guinea-pig experiments how little antitoxin was necessary in order to prevent effectively the infection in human beings.

Dr. W. H. PARK of New York said he would say one word in line with Dr. Coca's remarks. In testing animals, one might react, and one might not react. In regard to protective sera: the rabbit gives very feeble protective serum; the monkey gives better serum, but the horse gives as good, or even better serum than the monkey. Perhaps Dr. Abrahamson would say a word on that question. In his own experiments Dr. Park said he had first used virus from the brain, digested by trypsin, and then straight virus. Different animals showed a different period of development of antibodies and also a different degree.

Dr. JOHN KOLMER of Philadelphia asked if the serum had been used in the treatment of human infections.

Dr. H. ABRAHAMSON said he would add a word about rabbit poliomyelitis. He spent about six months inoculating animals to get signs of paralysis. He had not tested for immune bodies. He then subjected monkeys to injections of virus from rabbits. The virus of the 1916 epidemic was tested. The incubation period was variable. The control came down in six days. The animal injected with rabbit cord came down in fourteen days. One could not draw conclusions from these data. As regards horse injections horses had been used in two cases. The first injection was of brain and cord digested by trypsin; the second of emulsions of cords. The first injections were intravenous and then intraspinal. Later the serum from the first horse was found to neutralize virus one part to one. Monkeys were used to test how high the neutralizing power of the serum was. In his own work he had not had experience of horse serum in human cases. Dr. Neustaedter had used horse serum in three human cases and had got very bad reactions. It was very difficult to draw conclusions in poliomyelitis because some slight cases die and some serious cases get well. Rosenau's serum had been tested by them in their work and it was found to neutralize one to one. There must be some substance affecting the virus. It was killed every time with a 0.3 c.c. injection.

Types of Meningococci Concerned in Epidemic Infections.—Drs. A. PARKER HITCHENS and G. H. ROBINSON of Philadelphia presented this paper. The troops in this country were now undergoing the same conditions as the British troops at the beginning of the war. The work of English investigators was here of value, especially that of Gordon on the meningococci. He had typed the different strains, as had been done with the pneumococci, into four different groups. This work had been followed in the present experiments, and one hundred cultures, received from the first of the year, had been typed according to the Gordon method. The strains had been received from several concentration camps in this country. The cultures—from spinal fluids or from naso-pharyngeal swabs—were Gram negative cocci. They corresponded to a greater or less degree to Gordon's types, viz., I. parameningococcus; II. normal meningococcus; III. and IV. comparatively rarely found in this country. The grouping of the strains varied with different camps. Camp Jackson had one strain, type I; nine strains, type II; one strain, type III. Great Lakes camp showed: type I, one strain; type II, twenty-eight strains; two flavus; two undetermined. It was shown that each camp had a predominating type, but whether this was a true epidemic was not determined. The work was undertaken with the hope that specific sera might be evolved to counteract the types. Gordon had had excellent results with his specific strains. He found that if specific serum were given before the third day of the disease the mortality was only nine per cent.; if on the seventh day the mortality was fifty per cent. In testing the types the precipitin test had given valuable results, which were confirmed by cultural methods. Agglutination of strains seemed to give distinct differences which follow the types as laid down by specific sera, but what the relationship is was not yet conclusive. A rapid method of typing the meningococci was sought.

Influence of Active Normal Serum upon Meningococci.—Drs. JOHN A. KOLMER, I. TOYAMA, and T. MATSUNAMI gave this presentation. Fresh serum, it was stated, gave both normal and immune, had greater antibacterial properties than old serum, the latter having sustained a loss of antibodies as well as complement and opsonins. Antimeningitis serum, it was found, was rich in opsonins and had high phagocytic properties. Recovery from meningitis was in great measure due to this phagocytosis. The normal cerebrospinal fluid, it was found, was lacking in complement, and antibodies, such as agglutinins, hemolysins and antitoxins. It also lacks opsonins for meningococci. It was found, however, that fresh normal human and guinea-pig sera possess a well-defined amount of opsonin for virulent meningococci, the former possessing more than the latter. The amount was found to vary in different persons and in different guinea-pigs. Another conclusion was that the addition of fresh normal human or guinea-pig serum

to various antimenigitis sera, as prepared and marketed for administration, was found to increase definitely and uniformly the opsonic activity for various strains of meningococci. From studies of the opsonic activity, *in vitro*, of antimenigitis serum, as an index of curative power, one might conclude that fresh normal human and guinea-pig sera alone may possess curative properties when brought into direct relation with meningococci, and their addition increases opsonic value of stock sera on the market. A clinical test, the addition of 1 c.c. of fresh sterile human or guinea pig serum to each 9 c.c. of antimenigitis serum, before intraspinal injection, would be of value for the purposes of increasing phagocytosis of the microorganisms, especially in cases of severe and serum resistant meningococcus meningitis.

Influence of Active Normal Serum (Complement) upon Meningococci.—Drs. T. MATSUNAMI and J. A. KOLMER presented this paper. They found that the bactericidal activity *in vitro* of different antimenigitis sera was quite low. Fresh or active antimenigitis sera were somewhat more bactericidal than the same sera after inactivation by heating at 60 C. for thirty minutes. It was seen also that active normal human and guinea-pig sera are slightly bactericidal for meningococci. Horse-antimenigitis serum and normal human and guinea-pig sera were found to have a bactericidal activity, independent of complemental bacteriolysis. The test *in vitro* of normal and immune sera was best shown by a pipet method using small numbers of cocci and relatively large amounts of serum. The bactericidal activity of antimenigitis serum was increased by adding active normal human or guinea-pig serum. It was further found that the use of whole blood was of more effect than the use of sera alone. Agglutinations of meningococci occurred by using normal human and guinea-pig sera in dilutions up to 1:14, but not higher. The mouse test (Hitchens and Robinson) was of value for the determination of the protective and curative value of the serum. It was found that mice infected with virulent meningococci were not protected by normal active human and guinea-pig sera. The final conclusions from these experiments was that the addition of active normal human or guinea-pig serum (complement) to antimenigitis serum did not greatly add to bactericidal activity, as bacteriolysis was unimportant in antimenigitis serum; but it was found that opsonic activity (an important curative factor) was greatly increased by such addition. Moreover, it was considered worth while, in view of these findings, to use clinically an antimenigitis serum to which has been added active human or guinea-pig serum prior to intraspinal injections, especially in severe and serum resistant cases. In this respect human serum is superior to guinea-pig serum when proper aseptic precautions are maintained.

Dr. Wm. H. PARK of New York said he would like to ask a question as to the use of "specific therapy" in the treatment of cerebro-spinal meningitis. Could one get a serum for one type which would be stronger than the polyvalent serum? If one or two types could be injected into the horse at once and an antiserum produced, the advantage would be much greater than if one used two different horses for those types. Was there evidence that a polyvalent serum had been produced. If not, it would be advantageous to produce a serum for one or two types. In the pneumococcus serum it was necessary to make antisera against distinct types, but in this case a serum against one or two types would seem to be equally potent.

Dr. A. P. HITCHENS said Dr. Park's point was very well taken and he agreed up to a certain point. There might, however, be greater possibility of reducing the death rate through the use of specific sera. It was possible that there might be immunological variations of meningococci within the serological types. It was well known that with the best balanced sera obtainable one found cases of meningitis to resist their action. The meningococci isolated from spinal fluids in these cases were resistant in culture to the action of the polyvalent serum, although belonging to one of the well-known fixed types. These might be serum fast strains or not agglutinable strains. The Rockefeller Institute agglutination work would show that meningococci could not be accurately and sharply grouped within certain types,

but followed the order of a chromatic scale. There were an almost innumerable number of variations, although variations were slight. The problem of getting a polyvalent serum was therefore difficult. It was felt, however, that work should follow the lines of making a polyvalent type serum and find out if this would not confer more resistance in the refractory cases. It would be found necessary for this purpose to use many strains of meningococci. One could not select single strains of the four types and immunize a horse to these four strains, because there are an infinite number of variants within the types. In one case where the spinal fluid gave a specific reaction to the precipitin test the patient did not do well with the polyvalent serum. With a specific serum the case recovered. In regard to Dr. Matsunami's paper, those who were interested in active immunization against cerebrospinal fever would welcome the technique of Dr. Heiss. If even a low grade of immunity could be demonstrated this technique would be of considerable assistance.

Dr. PARK said that Dr. Hitchens had not exactly answered his question. Could not one horse be injected with two or three types, as well as with one type alone? In New York they were using the combined serum and had obtained reduction of mortality to 22 per cent. It would not do to take the time to type individual strains, as in pneumonia. Had it been proved that one could not produce a serum from a single horse that would answer to one or two strains? If not, there must be a horse for each strain. This would be very confusing from the laboratory standpoint.

Dr. HITCHENS said he thought he had replied to Dr. Park. If the number of antigens could be limited to four or five there would be no reason to think of specific sera. It was not possible to get sera equivalent to each four strains as high as for a single strain. In an antiserum for all strains it might be as high as against a single strain. If there were only five variants it would not be necessary to think of specific sera; but if, as had been suggested, there was a chromatic scale of variation—40 to 60 different varieties—one could not get sera as high for individual variants as if they were split into groups of four or five. There was, however, as yet no positive evidence in support of this theory.

Dr. C. KRUMWIEDE of New York said he was interested in the precipitin test diagnosis of type, but he was far from accepting its specificity. In his experience there would be reactions alike for types one and three and strain two would pick up strain four. Before progress could be made an easier way of differentiation must be found. The same agglutinations were found for strains one and three in 100 per cent. of cases. He felt a little hopeless about discovering a more specific test. The absorption tests showed no more than that the strains were either one or three. The question was, Which was it? The test would at least tell roughly whether it was one and three or two and four. As regards resistant cases, in one case that died they found that the serum was not agglutinated by the strain used in the case. They had been working on improvement of the opsonic index. They had found, as Dr. Kolmer had, that horse serum and human serum were both rich in normal opsonins and it was difficult to draw definite conclusions in this work.

Studies on So-called Cellular Anaphylaxis.—Drs. W. P. LARSON and E. T. BELL presented lantern slides illustrating experiments upon the livers of rabbits. The organs, after having been washed out to remove residual serum, were perfused with a solution of india ink, which clearly indicated the areas reached by the perfusing solution. The appearance of dark areas covered by the solution was extremely patchy; in some cases large areas had been covered, in others the perfusing experiment was very unsuccessful and only small spots had been touched. The slides were presented with the idea of showing that there was danger of making far-reaching conclusions upon the assumption of being able to wash out the organ fully before testing for the so-called cellular anaphylaxis.

Dr. J. F. ANDERSON, Brunswick, N. J., said that if the animal were sensitized to more than one protein there would be an inhibitory effect from the injection of a sublethal dose.

Dr. BRONFENBRENNER of Boston said if the injection was sufficient to hide the effect of the sublethal dose it

protects to one and a half to two doses of entire antigen.

Dr. J. F. ANDERSON said that was at variance with the results of Rosenau. They found that the protected case acted without the various sera. With various proteins, milk, etc., animals would respond within three hours. It was found that animals that recovered from the dosages would subsequently respond to a second or third injection. He would like to ask Dr. Bronfenbrenner if he tested out the sensitization of these animals by injections, following the injections in the intraperitoneal cavity.

Dr. A. P. HITCHENS asked if Dr. Anderson and Bronfenbrenner took into consideration the injection of the second antigen, during the anaphylactic period of the first dose.

Dr. A. F. COCA of New York said that Dr. Bronfenbrenner's experiments showed what had been called non-specific resistance and a non-specific anti-anaphylaxis. It had been shown that the resistance to anaphylaxis, if specific, was absolute. One could inject not only one-half, but many lethal doses in the desensitized animal. The animal becomes to the specific exactly as is the normal animal, but subsequently the animal could again become sensitized. For the purpose of Dr. Bronfenbrenner's argument it would be necessary to show that the desensitization was not non-specific but specific. Otherwise the experiment was in the same condition as that of Friedburger who obtained partial resistance by anaphylotoxin. That was what was called desensitization. The humeral theory was at a great disadvantage by not being able to explain the latent period after passive desensitization. Dr. Larson's paper, Dr. Coca said, was opposed to some of his own previous work. It would seem that this was conclusive proof that some of Dr. Coca's former conclusions were wrong, as far as they pertained to residual percentage of blood after perfusion. In defense of the whole argument he had showed that about one-half of the animals that are actively desensitized possess no antibodies that can be demonstrated in the blood. If half of the animal's blood is taken and injected into the normal animal, no passive desensitization can be obtained, nor enough antibodies left in the circulation to account for anaphylaxis that occurs after perfusion. Evidently in Dr. Larson's cases less than half the blood remained in the perfused animal, so that the experiments were conclusive and highly suggestive.

Mr. CHARLES WEISS of Philadelphia said that this was interesting in connection with some work on the effects of quinine. One series of guinea-pigs were treated with quinine to see if this drug would cause complement. It was found that the quinine evidently aided in saving nitrogen metabolism, as was seen after egg albumin injections.

Dr. G. H. A. CLOWES of Buffalo said he could substantiate Dr. Anderson's position. Eight years ago he had tried desensitization against hay fever in patients sensitive to spring and autumn fever. Timothy and ragweed were used and it was found that the skin test was strongly specific. Patients desensitized to timothy were not altered in their reaction to ragweed. Immunity developed only against the agent employed. The matter of antitryptic antitoxin was related to the matter of surface tension. The soaps, lecithins, calcium chloride and barium chloride played a part in this question. The non-specific interference was a matter of surface tension. He himself had obtained a marked desensitization to hay fever with a marked antitryptic index. This was followed up with care on account of its relation to the cancer question. The high antitryptic index was coincident with anaphylaxis and fell to normal after the hay fever period. The anaphylactic effects were due to increased permeability of the protein film.

Dr. J. BRONFENBRENNER said that he would begin by saying that calcium chloride and barium chloride did not produce specific anti-anaphylaxis. Dr. Coca was right when he said that Friedburger's effects were due to non-specific residue. What non-specific phenomena could effect anaphylaxis? There should be one single phenomenon underlying all this, because non-specific phenomena apparently affect specific phenomena. At least simultaneously there was seen to occur an antitryptic index and other causes that might prevent an

anaphylactic shock. An important point in the experiments would be to select a large dose of the specific antigen and the next lethal test injection would be simple. If that was not done there would be non-specific reactions. The exhaustion of the antibody, Friedburger's idea, was not proven yet, and further experiments would have to be made. Mr. Weiss' suggestion was valuable. It was interesting to see experiments showing that absolute perfusion was a very irregular thing. The speaker said he did not know what it depended upon. All the phenomena were not explained, but one could not exclude the fact of residual serum being there. In connection with surface tension most people would now be agreed upon that point and its connection with increased permeability of the cells.

Experimental Pollinosis in Guinea-Pigs.—Dr. HENRY ULRICH presented a summary of this work. The experimental animals were injected with pollen introduced into the nasal mucous membrane by means of a medicine dropper. A series of controls were kept, following the type of work by Sewall of Denver. The injected animals presented signs of hay fever, but never developed a real asthma. A certain periodicity was exhibited by a refractive stage and an irritable stage of the disease. Experiments in sensitization were begun with five animals using 5 grs. of pollen intraperitoneally. After this pollen was given in the nose. One group were not previously sensitized. A group of animals were injected with starch. It would appear from the experiments that the nasal mucous membrane has some digestive power for foreign proteins. In noting the results it was found that one group of animals were refractive to atoxic dose of serum. Three animals showed anaphylactic reaction. One control which received twice the dose that the sensitized animals received died within forty-five minutes from the toxic effects. It would seem that in hay fever the defensive mechanism in the nasal mucous membrane was in some way broken down.

Dr. G. H. A. CLOWES of Buffalo said he did not feel competent to discuss the paper as a whole, but he was interested in the results. In attempts made with human material it was tried to induce sensitization in individuals who were not sensitive, and it was unsuccessful. This would give a clue to the work upon this mysterious condition.

Dr. A. F. COCA of New York said that one must recognize this as a revolutionary piece of work. He had, with Dr. Cooke, carried out experiments of a similar nature. It could be said that thousands of people had received injections of horse serum, but no one had ever reported that such persons had become sensitive to horse serum. Dr. Cooke had injected human beings with pollen extracts to which they were not sensitive, but had never found them to be affected by hay fever due to the pollens injected. They had tried to sensitize guinea-pigs, in a large series of cases, and had not succeeded. All of the pollen was not used, but pollen extracts of high concentration. Human beings are naturally sensitive to those substances. Guinea-pigs can become sensitive to certain proteins. Pigs receiving injections of egg white, after previous injections, died in half an hour from anaphylaxis. Any antigen would kill artificially sensitized animals. This was different to natural sensitization, as the same systems were not affected in the two. Human beings might show certain kinds of sensitization, but not the symptoms of natural sensitization. In one case the muscular tissues are saturated with the antibodies; in the other the epithelial tissues which are affected are saturated with antibody like substances.

Dr. J. F. ANDERSON said a good many years ago it was demonstrated that animals could be sensitized by instillations in the nose so as to respond with symptoms of anaphylaxis. Had Dr. Ulrich confused the sensitization to protein with the sensitization to pollen. These were two entirely different propositions and opened a field for large experimentation.

Dr. A. P. HITCHENS said Dr. Smith had tried to sensitize both guinea-pigs and rabbits and was never successful. He wondered if Dr. Ulrich would tell what pollen was used and the method of extraction of the pollen. All pollen used was found by himself to be

very badly contaminated and had many bacteria of different kinds. Unless it had been cleaned (by means of which they were unable to devise) the bacterial contamination might play a large part in the phenomena which resulted.

Dr. G. H. A. CLOWES said they had found contamination by bacteria and minute insects. Reactions to these might be introduced. They had never succeeded in getting reactions in normal individuals.

Dr. G. SMITH of Philadelphia said that not only had they instilled pollen into the nose and mucous membranes of normal animals, but they had tried to injure the mucous membranes to see if they would respond more after injury. They were shut up in glass cages in which pollen was kept circulating by means of the electric fan. No sensitization was obtained.

Dr. H. ULRICH said that the pollen was washed in acetone and the sterile pollen was injected into the peritoneal cavity and never showed any growth. It was cleansed and kept dry in the powder form. One-fifth mg. in suspension was taken care of well by the guinea-pig. Pollen extracts were then introduced in the nose. In regard to whether this sensitization was to pollen or to protein, one should consider the mucous membranes in the nose. These contained defensive mechanism which was broken down in hay fever.

Influence of Arsenobenzol and Mercury upon Antibody Production.—Drs. JOHN A. KOLMER and I. TOYAMA of Philadelphia read this paper. The possibility of certain drugs acting as antigens had been the theme of several studies by different workers. The antigenic action of drugs might account for acquired drug tolerance and also aid in resistance to infection by stimulating antibody production against micro-parasites apart from direct action of the drug on the parasite. The latter phase of the subject was the one particularly dealt with by the authors. Considerable evidence would point to the conclusion that many drugs exerted a stimulating action on antibody production by the tissues. Such drugs as arsenous anhydrid, phosphoric acid and mercuric chlorid, administered by mouth, were found to act in this manner. Salvarsan appeared to stimulate agglutinin production, according to some workers. The present experiments were conducted on rabbits, to determine if small daily doses of arsenobenzol and mercuric chlorid tended to increase antibody response to alien erythrocytes or to typhoid bacilli. After a series of experiments, five in all, on a large number of rabbits, and control animals, it was found that no increase of antibody production was shown, after injections of arsenobenzol or mercuric chlorid. On the contrary, it would seem that there was a lowering of antibody production, probably due to lessening of resistance by toxic effects. Further experiments, however, were in progress, upon the action of these drugs in experimental trypanosome infections. It was felt that such work should be done upon human sera, as work upon the sera of lower animals might not be a true index in human cases. The importance of the subject would demand careful experimental work in this direction.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

Clarksburg, November 21, 1917.

(Concluded from page 750)

SURGERY.

1. Describe Potts' fracture of the lower extremity.
2. How does a carbuncle differ from a boil?
3. Describe a reduction of the inferior maxillary bone.
4. Give the treatment of fracture of the ribs.
5. What are the methods of controlling hemorrhage?
6. What is a sprain of the ankle joint? Symptoms and treatment?
7. What are the symptoms of strangulated hernia?
8. What is shock? And its cause?
9. How are burns classified? Give treatment.

10. State the distinction between antiseptic and aseptic wound treatment.

11. Describe an operation of circumcision.

12. What are the causes of intestinal obstruction?

SPECIAL MEDICINE.

1. Name the extrinsic muscles of the eye and give their motor nerve supply.
2. Give diagnosis and outline treatment for acute catarrhal conjunctivitis.
3. Give fully the prophylactic treatment of ophthalmia neonatorum.
4. Give care of an eye injured by a lime burn.
5. Describe paracentesis of the drum membrane and when should it be done?
6. Give treatment for chronic suppurative otitis media.
7. What is tinnitus aurium? And name five general causes.
8. Give treatment for acute coryza.
9. Give diagnosis and treatment for acute follicular tonsillitis.
10. How can you differentiate *positively* chancre from chancroid.
11. Treatment of cystitis in the female, and name the most common organism.
12. Differentiate between suppression and retention of urine. Give treatment of each.

ANSWERS.

SURGERY.

1. *Pott's fracture* is very common, and is due to indirect violence, such as turning over on the inside of the foot. The strain tears through the internal lateral ligament of the ankle or tears off the tip of the malleolus; then the astragalus is pressed against the inner side of the external malleolus by the continuation of the violence. The fibula is overbent, and breaks about three inches above the tip of the malleolus. At the same time the foot is displaced outward or outward and backward. In many cases, however, the displacement is slight.

Treatment.—"An anesthetic should always be given, and the fracture reduced by relaxing the calf muscles and applying traction to the foot. The limb must then be fixed on the back splint, with side splints in addition. The foot must be at right angles to the leg, the bony points in line, and the posterior displacement corrected. The surest way of maintaining the foot in good position is to at once apply plaster of Paris. Other splints used are Dupuytren's and Syme's horseshoe splint. Massage and passive movement at the end of ten days are advisable, the fragments being firmly grasped to prevent displacement."—(*Aids to Surgery.*)

2. "*Furuncles and carbuncles* result from infection with the *Staphylococcus aureus*, which enters the orifices of the ducts of the skin under the influence of friction and pressure. A *furuncle* results when the infection is located in a hair follicle or sebaceous gland. A hard, painful, conical swelling develops, to which, so long as the skin retains its normal appearance, the term 'blind boil' is applied. Usually, however, the skin becomes red, and after a time breaks, giving exit to a drop or two of thick pus. After an interval of from six to ten days a soft white slough is discharged; this is known as the 'core,' and consists of the necrosed hair follicle or sebaceous gland. After the separation of the core the boil heals rapidly, leaving a small depressed scar. *Carbuncle* may be looked upon as an aggregation of boils, and is characterized by a densely hard base and a brownish-red discoloration of the skin. A carbuncle is usually about the size of a dollar piece, but it may continue to enlarge until it attains the size of a dinner plate. As time goes on several points of suppuration appear, and when these burst there are formed a number of openings in the skin, giving it a cribriform appearance; these openings exude pus. The different openings ultimately fuse and a large adherent, grayish-white slough is exposed. The separation of this slough is a tedious process and the patient may become exhausted by pain, discharge, and septic absorption. When the slough is finally thrown off a deep gap is left, which takes a long time to heal."—(*Thomson and Miles' Surgery.*)

3. To reduce dislocation of inferior maxillary bone:

The surgeon places his thumbs, well protected by a towel, on the molar teeth or behind them, presses the angles of the jaw downward while he elevates the chin with his fingers; and by this manipulation the condyles of the jaw usually slip back into place with a snap. After reduction of the dislocation the jaw should be fixed for a week or ten days by a Barton's bandage or a four-tailed sling.

4. *Treatment of fracture of the ribs:* Strips of plaster reaching from the spine to the sternum should be placed over the injured side during deep expiration. The strips should overlap, and a bandage should be put on over the plaster. If the fracture is due to direct violence, no strapping should be used, but the patient kept still by placing sand bags on either side. Ribs always unite readily.

5. *METHODS OF CONTROLLING HEMORRHAGE.*—*Mechanical treatment* includes: Elevation, pressure, torsion, ligation, compression, aeupressure, and forced flexion of limb. *Therapeutic treatment* includes the use of: Heat, cold, styptics, and the cautery.

6. A sprain of the ankle joint is an ill-defined injury of that joint, in which the tendons, muscles and synovial membranes are more or less involved; sometimes there is a contusion as well. The symptoms are pain, tenderness, swelling, ecchymosis, impaired movement, and inability to walk. The treatment consists of massage and strapping by adhesive plaster. A treatment that, according to Gibney, "involves no loss of time, requires no crutches, and is not attended with any impairment of functions," is as follows: A number of strips of rubber adhesive plaster, about 9 to 12 inches in length and of appropriate width, are prepared. Beginning at the outer border of the foot, near the little toe, the first strip partially encircles the joint, and ends behind the foot. The second strip is begun on the inner side of the foot and is applied on the opposite side, nearly meeting the first strip behind. Other strips are applied in like manner, each one overlapping the last and crossing its fellow of the opposite side in front, so that the ankle is snugly and smoothly incased, care being taken not to encircle completely the joint with any one strip. After having bound the foot firmly, it is well to add one broad strip, running around the foot from the internal side of the leg down the internal side of the foot, across the plantar surface, and up the outside of the leg, "as much as possible to take the place of the middle fasciculus of the external lateral ligament, which is so often the one most injured." It is a good plan to place a pad of absorbent cotton over the external malleolus and in the fossa below, to prevent undue pressure and chafing. Any one of the injured ligaments may receive a similar reinforcement from an extra strip. Then apply a roller smoothly over the entire surface, allowing it to remain until the plaster takes firm hold.—(*Pocket Cyclopaedia*.)

7. *Symptoms of strangulated hernia: General.*—"Severe pain comes on suddenly after some effort, at first referred to the umbilicus, and subsequently to the site of the hernia. This is accompanied by some shock. The pulse is weak, and, though slow at first, becomes rapid; the skin is cold and clammy; vomiting occurs, and soon becomes frequent and fecal smelling. Constipation is complete, though both feces and flatus may be passed at first from the lower bowel. The patient generally becomes exhausted from the vomiting and inability to take food. When gangrene occurs the temperature becomes subnormal, the pulse very rapid and weak, and the patient dies of toxemia from the general peritonitis which follows gangrene. *Local.*—A tumor forms at one of the hernial sites; or more often the patient has been the subject of a hernia, which he now finds to be irreducible, tense, tender, and without impulse on coughing. If allowed to persist the sac and coverings become gangrenous."—(*Aids to Surgery*.)

8. *Shock* is the name given to a sudden and general depression of the vital powers, due to some strong stimulation (such as injury or emotion), acting on the vital centers in the medulla and producing vasomotor paralysis. Shock is *primary* when the symptoms appear promptly; it is *secondary* when the symptoms do not appear for several hours (often observed after railway accidents, intoxication, etc.)

"The explanation of shock usually accepted, largely on the authority of Crile and Mummery, is that the

paralysis or exhaustion of the vasomotor center in the medulla results in a lessening of the vascular tone, particularly that of the arteries, and a marked fall in the blood pressure. Most of the blood leaves the arteries and collects in the large venous trunks, especially those of the abdomen, and there is thus produced an anemia of the brain and of the superficial parts of the body. At the same time the right side of the heart becomes overloaded and impeded in its action. According to J. D. Malcolm the disturbance of the vasomotor center results, not in dilatation, but in contraction of the arteries. At first the superficial vessels are constricted, and if the exciting cause is kept up this condition spreads back to the larger vessels, so that the blood is driven out into the tissues and back into the abdominal veins."—(Thomson and Miles' *Surgery*.)

9. *Degrees of Burns.*—Dupuytren's classification: *First degree*, reddening of the skin. *Second degree*, blistering. *Third degree*, destruction of the epidermis, Malpighian layer, and papillae of the derma. The sensitive nerve terminals are exposed; consequently this is the most painful degree. The sweat and sebaceous glands and hair follicles are not destroyed, and from these epithelium spreads in healing, so that repair is rapid, and the scar is not a contracting one. *Fourth degree*, the whole thickness of skin and part of the subcutaneous tissues are destroyed. *Fifth degree*, the muscles are injured. *Sixth degree*, the whole limb is charred.

Treatment.—General: If carbonic-oxide poisoning is present, artificial respiration and administration of oxygen. For shock, opium and stimulants. Local.—For burns of the first degree, powder with boric acid. Puncture blisters, and cover the part with an antiseptic dressing. Burns of deeper degrees than the second must be made aseptic with 1 in 1,000 perchloride of mercury. Carbolic acid is absorbed readily, and must not be used. Antiseptic gauze dressings should then be used. Pieric acid (20 grains to 1 ounce of water) is used as a dressing. It lessens the pain, and can be left on two or three days. The continuous bath may be used. If the burn be of any size it should be skin grafted, as the scars of burns contract very much, and may produce deformities.—(*Aids to Surgery*.)

10. *The antiseptic system* aims at the destruction of bacteria, and relies largely upon the action of chemical bactericides, wounds themselves being treated with such chemicals. Instruments are prepared by soaking in, dressings by impregnation with, skin by scrubbing with, antiseptics. The air is treated by an antiseptic spray, and the wounds are constantly bathed in antiseptic solutions.

The aseptic system aims at the prevention of wound infection by excluding bacteria from the wound, relying almost entirely on heat for the destruction of germs, and using no chemicals in contact with wounded tissues. Instruments are boiled, dressings are steamed, skin surfaces are excluded from wound contact.—(*Synopsis of Surgery*.)

11. "*Circumcision* is performed by drawing the prepuce forward and then enclosing it in a pair of clamp forceps placed obliquely just in front of the glans. The prepuce is next divided with a straight bistoury, and the forceps removed, when the skin and mucous membrane retract. The mucous membrane, if adherent, is dissected loose from the glans; if redundant, it is trimmed with scissors to make it correspond to the line of skin incision; the cut edge of the mucous membrane is next fastened to the cut edge of the skin by a few sutures of silk or catgut."—(Wharton's *Minor Surgery*.)

12. *Causes of Intestinal Obstruction:* Strangulation, kinking, volvulus, intussusception, foreign bodies, tumors in the intestinal wall or pressure due to tumors outside the bowel, fecal accumulation, and stricture.

SPECIAL MEDICINE.

1. *The extrinsic muscles of the eye* are: Levator palpebrae superioris, superior rectus, inferior rectus, external rectus, internal rectus, superior oblique, and inferior oblique. The external rectus is supplied by the sixth cranial nerve (abducens); the superior oblique, by the fourth cranial nerve (trochlear); and the remaining five muscles, by the third cranial nerve (motor oculi).

2. *ACUTE CATARRHAL CONJUNCTIVITIS. Symptoms:* "Hyperemia, profuse lachrymation, epiphora, a profuse discharge, sensation of sand in the eye, and sometimes

photophobia. *Treatment:* Astringent and antiseptic washes are of value. Ascertain the underlying cause, if possible, and remove it. Anointing the lids with pure or medicated vaseline every evening is necessary. Alum, tannic acid, silver nitrate, and zinc sulphate are valuable as astringents. In intractable cases a 50 per cent. solution of boroglycerid in glycerin should be applied once daily.—(*Pocket Cyclopaedia*.)

3. **OPHTHALMIA NEONATORUM.** *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burned.

4. *For chemical burns of the eyeball:* The treatment consists in the complete removal of the caustic substance as soon as possible. Solid particles are removed with cotton or forceps. Then the conjunctival sac is washed out with solutions which tend to neutralize the corrosive substance or render it insoluble. In the case of lime, mortar, or caustic alkalies, we flush out with a solution of boric acid, or we may wash out the eye with oil. Subsequently we use cold compresses, atropine, and sometimes a bandage. After the loosening of the eschars, we must separate the adhesions frequently. Symblepharon often occurs notwithstanding the greatest care.—(*May's Diseases of the Eye*.)

5. *Indications for paracentesis of the membrana tympani:* To evacuate pus in the tympanum (and so to relieve pain, limit the infection, shorten the disease, and prevent complications); for enlarging perforations which are too small to allow adequate drainage; it is employed also in certain catarrhal and inflammatory conditions of the ear.

The parts are to be sterilized, an anesthetic (local or general) given; and the incision is then made with a slender, sharp-pointed knife. A speculum and adequate illumination will be necessary. The particular quadrant which should be incised depends upon the condition calling for the operation. The incision should be made sufficiently long; a mere puncture is not sufficient. If possible the incision should be so placed that the opening will extend from near the floor of the canal upward and through the bulging portion of the membrane. The surgeon should avoid touching the auditory ossicles.

6. *Treatment of chronic purulent otitis media:* "Cotton must never be worn in the discharging ear. The discharge must be mopped out, but if very thick and copious, syringing by means of sterile water or sterile water containing salt (gr. 5-5 1) or carbolic acid (1:40), once or twice in 24 hours in bad cases is permissible. After mopping the ear, 10 drops of an antiseptic solution may be instilled. Formalin solution (1:1000-1:2000), carbolic acid solution (1:40), or, if granulations are present, absolute alcohol may be dropped in and allowed to remain for a few minutes, and then turned out into a towel. This treatment should be continued once or twice a day in very bad cases, and less often when the discharge decreases. If, after several months, improvement does not take place removal of the ossicles under general anesthesia may be necessary."

7. *Tinnitus aurium* is the name given to any subjective sounds heard in the ear. The chief causes are: Neurasthenia, impacted cerumen, otitis, and other ear diseases; Menière's disease, obstruction of the Eustachian tube, anemia, leukemia, cerebral hyperemia and anemia, arteriosclerosis, gout, digestive disorders, excessive use of alcohol or tobacco, and the use of certain drugs such as quinine or salicylic acid.

8. *Treatment of acute coryza:* Quinine sulphate (10

grains), with morphine sulphate ($\frac{1}{4}$ grain), or Dover powder (5 grains) will often abort an attack. A hot foot-bath, rest, and saline laxatives aid materially. Tincture of belladonna (2 minims every hour, until 6 doses are taken, then half this quantity until the physiological effects of the drug are manifest); if much fever is present tincture of aconite (5-minim doses) may be added; camphor is also serviceable. Cleaning the nose with Dobell's solution is of value.

9. *Acute follicular tonsillitis.* The onset is accompanied by chills, rigor, fever, severe pains in back, limbs and throat, dysphagia, and tenderness at the angle of the jaw. The tonsils are swollen and are studded with yellowish-white points; pain in the ear is common. Coated tongue, anorexia, depression, rapid respiration and pulse are also noted. The condition is to be diagnosed from diphtheria. In this latter condition the fever is not nearly so high, there is a white membrane which spreads to the pharynx uvula, and soft palate, which leaves bleeding points when it is removed, and which contains the bacillus diphtheriae; this membrane recurs after removal.

Treatment of follicular tonsillitis.—The patient should be in bed; calomel (followed by a saline) should be given to open his bowels; sodium salicylate, gr. x-xv, q. 3 h., may be given; hot fomentations externally are of service; potassium chlorate may be used as a gargle or sucked, in the form of tablets. Antiseptic sprays have been used; if an abscess forms it should be opened. Tonics and nourishing food are indicated during convalescence.

10.

CHANCRE.	CHANCROID.
Has a period of incubation; ten days to three weeks.	Has no period of incubation.
Looks like a superficial erosion.	Is "punched out" and excavated in appearance.
The edges are sloping.	The edges are undermined.
The floor is smooth, shining, and red in color.	The floor is uneven, "worm-eaten," and yellow in color.
The secretion is serous and profuse.	The secretion is purulent and autoinoculable.
The induration is cartilaginous and sharply limited.	There is no induration, but the sore may be surrounded by a zone of edematous infiltration, not sharply limited.
The neighboring lymphatic glands are indurated, painless, freely movable beneath the skin, not matted together, and do not suppurate unless infection of the chancre has occurred.	If the neighboring lymphatic glands are involved, they form an inflamed, painful mass, which usually suppurates; the overlying skin becomes red, tender, and hot.
The tissues around the lesion are purplish in color from venous congestion.	The tissues around the lesion are bright red in color from acute inflammation.
Spirochetæ are found in the discharge.	No spirochetæ are found in smears.

—(*Hayden's Venereal Diseases*.)

11. *Treatment of cystitis in the female:* Rest in bed, the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz bath; irrigation of the bladder with an antiseptic solution; hot fomentation and vaginal douches are often helpful; sometimes intravesical medication is necessary.

The most common organisms are: *Bacillus coli communis*, gonococcus, and bacillus tuberculosis.

12. *Retention of urine* exists when the bladder contains urine which cannot be voluntarily expelled.

Suppression of urine exists when the kidneys fail to secrete urine.

Treatment of retention of urine: Hot baths, suppositories of morphine and belladonna, may first be tried. Failing these, a soft rubber catheter should be passed; if this fails a filiform catheter may be tried; if the prostate is enlarged, a metallic catheter (prostatic) should be tried; failing these methods, suprapubic aspi-

ration, or cystotomy (suprapubic or perineal) may be tried.

Treatment of suppression of urine: This depends upon the cause. Generally warm baths, pilocarpine, and measures to induce excretion from the skin should be employed. Diuretics should not be given, and laxatives must be employed cautiously. In cases of renal congestion, wet cupping over the loins, or venesection (in robust individuals) may be tried. If a calculus is present in the kidney or ureter, it must be removed.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF EXAMINATION†
Alabama*	S. W. Welch, Montgomery	Montgomery, July 9
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix, July 2
Arkansas	T. J. Stout, Brinkley	Little Rock, May 14
California	C. B. Pinkham, Sacramento	San Francisco, June 25
Colorado	David A. Strickler, Empire Building, Denver	Denver, July 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven, July 9
Delaware	J. H. Wilson, Dover	Wilmington, June 18
Dist. of Col.*	F. P. Coneland, Washington	Washington, July 9
Florida*	W. M. Rowlett, Tampa	Jacksonville, June 18
Georgia	C. T. Nolan, Marietta	Atlanta, May 30
Idaho*	Charles A. Dettman, Burke	Pocatello, June 3
Illinois	F. C. Dodds, Springfield	Chicago, July 9
Indiana	W. T. Gott, Crawfordsville	Indianapolis, July 9
Iowa	G. H. Sumner, Des Moines	Des Moines, June 18
Kansas	H. A. Dykes, Lebanon	Topeka, June 18
Kentucky	J. N. McCormack, Bowling Green	Louisville, May 28
Louisiana	E. W. Mahler, New Orleans	New Orleans, June 6
Maine	F. W. Searle, Portland	Portland, July 2
Maryland	J. McP. Scott, Hagerstown	Baltimore, June 18
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston, May 14
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor, June 11
Minnesota	T. McDavitt, St. Paul	Minneapolis, June 4
Mississippi	J. D. Gilgyley, Jackson	Jackson, June 17
Missouri	G. H. Jones, Jefferson City	St. Louis, Oct. 1
Montana*	S. A. Cooney, Helena	Helena, Oct. 1
Nebraska	J. J. Hompes, Lincoln	Lincoln, June 24
Nevada	S. L. Lee, Carson City	Carson City, June 18
N. Hampshire	Walter T. Crosby, Manchester	Concord, June 18
New Jersey	A. MacAlister, Trenton	Trenton, June 18
New Mexico	R. K. McClannahan, East Las Vegas	Santa Fe, New York, May 21
New York	G. M. Wiley, Univ. of State of New York, Albany	Albany, Syracuse, Buffalo, Raleigh, June 24, July 2, June 4, July 9, July 2, July 9
N. Carolina	H. A. Royster, Raleigh	Raleigh, June 24
N. Dakota	G. M. Williamson, Grand Forks	Grand Forks, July 2
Ohio	H. M. Platter, Columbus	Columbus, June 4
Oklahoma	J. J. Williams, Wetherford	Oklahoma City, July 9
Oregon	B. E. Miller, Portland	Portland, July 2
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, July 9
Rhode Island	B. U. Richards, Pawtucket	Providence, July 4
S. Carolina	H. E. Boozer, Columbia	Columbia, June 11
S. Dakota	P. B. Jenkins, Waubay	Deadwood, July 9
Tennessee	A. B. DeLoach, Memphis	Memphis, Nashville, Knoxville, June 14, July 18
Texas	M. F. Bettencourt, Mart	Austin, June 18
Utah	G. F. Harding, Salt Lake City	Salt Lake City, July 1
Vermont	W. Scott Nav, Underhill	Burlington, July 9
Virginia	J. W. Preston, Roanoke	Richmond, June 18
Washington*	C. N. Suttner, Walla Walla	Tacoma, July 2
W. Virginia	S. L. Jepson, Charleston	Wheeling, July 9
Wisconsin	J. M. Dodd, Ashland	Milwaukee, June 25
Wyoming	H. E. McCollum, Laramie	Thermopolis, July 10
National Board	J. S. Rodman, Philadelphia	Fort Riley, Kan.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

INTERNATIONAL CLINICS. Vol. I, 28th Series, 1918. By H. R. M. LANDIS. 298 pages. Illustrated. Price, \$2.00. Published by J. B. Lippincott Company, Philadelphia and London.

CANCER COMMISSION OF HARVARD UNIVERSITY. FIFTH ANNUAL REPORT OF THE COLLIS P. HUNTINGTON MEMORIAL HOSPITAL FOR CANCER RESEARCH AND OF THE LABORATORIES, 1916-1917. For the Year ending June 30, 1917. 63 pages. Boston, Mass.

Miscellany.

Items of Life in Germany.—In an issue of *La Presse Médicale* some time ago were given a number of items of daily existence in various parts of Germany. Thus at latest accounts the weekly ration for Hamburg remained at 4½ lb. of bread, 6½ lb. of potatoes, and 8 oz. of meat with bone. The excess of bran in the bread having been accused of causing gastroenteric disturbance (Leipzig), the bran was shot through fine sieves before its addition to bread. With the bran cells thus completely dissociated the disturbance ceased. Game killed by hunters still gravitates to the tables of the well-to-do. The arrival of milk in Berlin continues to diminish and children receive only a pint daily. Potatoes are plentiful but of poor quality because of the continued rains. Freight cars are stalled at the terminals (Munich), because of a lack of dump carts, and the potatoes are too soiled to be placed in cellars. The fruit crop was abundant, but owing to scarcity of labor much of it rotted on the trees. On account of the scarcity of leather, shoes were to have wooden soles and cloth uppers. All shoes will be low cut and without high heels. Those who gather fodder (nettles) now receive double pay (28 marks per 220 pounds of dry stalks). Hair combings must be saved and this order frightens the women who fear that the hair braids of the little girls will next be commandeered. Sewing thread is as hard to get as onions. Breweries get but 15 per cent of barley, one-third the amount before the war, and beer is becoming rare, especially for the civilian.

The Campaign Against Venereal Diseases in Great Britain.—In the course of a recent speech at Manchester Mr. Henry Fisher, president of the Local Government Board, referring to the recommendations of the Royal Commission on Venereal Diseases, said that the local authorities of the country had already made a magnificent start by putting them into operation. These recommendations were for the provision of laboratories, open freely to all local doctors for the making of tests, of clinics where the most modern treatment could be obtained free of cost, and of the best known remedies for use by all qualified doctors in the area. The regulations were only issued about fifteen months ago. Yet out of 145 county and county borough councils no fewer than 135 had already submitted schemes to the Local Government Board. Of those schemes 112 had been approved, and 111 were actually being administered. It was a little too early yet to give figures. These would be published soon. But in the next nine months ended September, 12,000 hitherto unknown cases were treated in the London center alone, and it was calculated that by the end of the year this number would be increased to 16,000. Manchester's contribution was the establishment of centers at all its principal hospitals with others to follow if necessary; twenty clinics for out-patients, and the coming provision of beds for out-patients who might need them, and in addition to this a capital laboratory in connection with the university, where splendid work was being done.

PROBING THE MIND.

SECOND REPORT.*

THE INTELLIGENCE AND ITS EXAMINATION.

By J. VICTOR HABERMAN, A.B., M.D., S.M.D.,

NEW YORK.

INSTRUCTOR IN PSYCHOTHERAPY AND CLINICAL PSYCHOLOGY,
COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY,
VISITING PHYSICIAN, DEPARTMENT OF NEUROLOGY,
VANDERBILT CLINIC, NEW YORK.

THE subject of the Intelligence Examination, though slowly fostered over a period of several decades and for the most part within the circle of medical science, stimulated, in fact, by its needs, has suddenly been popularized with us and boomed, so to speak, and, stripped to simplicity, made a "cinch course" in the curriculum of What Everyone Should Know.

Strange to say, in this popularizing movement the men who should have been most concerned, the physicians, took no interest whatsoever and had nothing to offer, criticise, or condemn. As a result, we now find the subject no longer within the circuit of our activities, no longer in the tradition of mental pathology, but fallen prize to the energy and enthusiasm of the psychologist—and only too often of the *psychologist* or "layman clinician" whose ardor has forced the thing into the limelight and whose mock heroics, if we do not call a halt, will soon do it to death. Incidentally, and as a result too, we awaken to the fact that we have trained few if any within our own ranks to supervise or guide this work, and that we are slowly coming to the inevitable conclusion that the present layman's methods and goal are not and cannot safely be our own.

There would be little as yet irreparable and no cause for alarm if it were not that this popularizing and laymanizing has taken on a most astounding momentum, and is not only sweeping conservatism and dignity from the *clinic*,¹ but in this branch of work is relegating its very fundamentals, namely, pathology, quite out of mind. At every turn you will hear the subject chatted of and find someone ready to make a Binet test and cull you a diagnosis in terms of feeblemind—but nowhere a *physician*, but really scarcely one, psychologically trained and with enough actual knowledge of the matter to weigh the facts or sift out the real from rubbish.

Is the physician really aware of how the problem stands? Does he ever stop to think of the profound

*For first report see MEDICAL RECORD, December 1, 1917.

difficulties on the one hand the neurologist and psychiatrist avers in fathoming mental pathology and in differential diagnosis of the same, the acknowledged perplexity in grasping the shifts and tangles of abnormal mind, and on the other the Binet-testing snugness of the present-day intelligence examination that every schoolgirl is urged to ply and that has become a five-minutes side-issue at our schools, clinics, and courts? To me it is amazing.

Whatever the need and problem of psychologist and pedagogue, that of the physician is not fulfilled by the Binet test² and the present popularized method of mental examination, and a rapid review of the facts will, I am sure, make this sufficiently clear.

There have been various methods of estimating the intelligence. The simplest has been the application of some single test, *i.e.* the testing of some single ability, the passing of which was presumed to parallel the general competence. Or, again, one tested such special capability, as *combination*, easily elected the criterion of mental endowment. The well-known Ebbinghaus completion test or the Möller fable interpretation are examples.³

Instead of the single test brief series in combination have been used as the De Sanctis set, or questionnaires and inventories of knowledge (facts gathered and remembered).

Another method has been that of testing separately the various mental traits or faculties, or constituent functions of intelligence (memory, comprehension, combination, etc.), and endeavoring to learn in just which the defect or deficiency, if present, existed. This is possibly the oldest, and most widely employed abroad, and the method in whose tradition and development the foremost of the continental neurologists and psychiatrists have had a hand. In this method a longer series of tests is used, the best known being that of Rieger, Kræpelin, Sommer, and especially the tests of Ziehen.

There is a third important method, that devised by Binet and Simon, in which a set of five or six questions is given, each group assumably corresponding to a definite pedagogical year, the results of examination showing not the deficiency or defect in any of the constituent functions, but the *age average of general intelligence* obtaining. The questions employed are "standardized" by presuming that if 75 per cent. of children of a certain age pass the test it must be normal for that age. This is the method of *age-average-gradation* of intelligence.

There is finally the "psychological profile" of Rossolimo,⁴ a highly interesting but oversystematization of the facultative test method (see below),

the "Point scale" of Yerkes and Bridges, the Meumann, Bobertag, and Terman arrangements of the Binet method, and other less important forms.

The fact that one method after the other is being evolved, that criticism of all has been sharp, that even within each camp there are differences and continued revisions, makes it decidedly ominous that the proper method has not yet been found, and that those enumerated do not suffice.

At the same time, a close scrutiny of the subject brings one soon to the conclusion that there is not only good and bad, and an essence of something similar in all of them—that is, elements of each in all—but certain significant essentials lacking in each.

The Facultative Test Method.—Let me first discuss the second mentioned method, that of testing the constituent function or faculties of intelligence. To some of our psychologists the mere mention of the word "faculty" connotes something analogous to phrenology—and at once an old time and discredited locality or "faculty psychology" is thought of in which each faculty was presumed a functioning entity. Personally I have never used the word in this absurd sense nor have any of the men mentioned above as sponsors for this test method ever given the least indication that they had any such conception. Empirically, however, we have learned that the mental make-up can be separated and sub-separated into components or faculties or elements—call them what you will—which, however interrelated and combined, can be separately discerned in individual after individual, normal and abnormal, and within certain measure readily appraised.

In the clinic work of years these components have been defined, circumscribed and compared, and have finally become part of the common language of neurology and psychopathology (and psychology for that matter), and later of remedial pedagogies besides. When therefore one speaks of memory, comprehension, combinational ability, feeling, attention, etc., one is not working with "assumed mental faculties," as F. N. Freeman puts it in his review (*Psychol. Bulletin*, July, 1917), but is employing the most legitimate of terms and such as our fellow scientists and colleagues trained in psychopathology avowedly understand.

Indeed abnormality of one or other of these elements is often the first danger signal of nervous or mental trouble to come, and where such abnormalities are more outspoken, become at times the very differentiae of diagnosis—the special tags of pathological pictures, as we clinically know them.

What, then, are these elements or trends of mind that we sunder out from the general mind make-up with the hope of thereby understanding mental life and unraveling its tangles in disease? First of all we must distinguish two large groupings, the one dealing with *ideas*, their formation, retention, comprehension, and combination; the other with the phenomena of feeling, affect, appetite, inhibition, thought tendencies, and impellants. The former are the factors comprising *intelligence*;^a the latter the levers of will, and consequently of action and deed. These latter, too, are the components that give color and quality to the individual—that constitute *character and personality*.

These two groups of factors, though they influ-

ence one another, must be kept clearly apart in our task of examination and evaluation. When abnormality is found in the former, we have the clinical pictures of mental deficiency, stupidity, defect or feeble-mindedness (this last being divided according to intensity into debility or morosity, imbecility, and idiocy). When abnormality occurs in the latter, we speak of *psychopathy*, and this very extensive domain is roughly rubriced into the clinical classification of psychoses, psychopathic constitutions, and the psychoneuroses or neuroses. (The subject of psychopathy will be taken up in a subsequent report.)

Normal intelligence, even of great excellence, may exist alongside of psychopathy, even of severest type. This must be distinctly remembered. On the other hand, psychopathy may influence the intelligence profoundly, especially such abnormalities as of the attention and feeling—pathological shyness, fright, anger, emotional confusion, or inhibition (inhibition of ideas, or of expression, katatonic perseveration, etc.), affective impulsions,* et cetera. Hence, every intelligence examination should be preceded (or controlled) by an investigation of these factors and a careful anamnestic inquiry, for failure in tests may depend wholly upon psychopathic trends (or momentary motor disequilibrium^b), the intelligence itself being intact.

Again, defective intelligence may occur without the slightest psychopathy; in such cases, however, if the intelligence defect is severe, the lack of the higher reasoning powers (analysis and combination) may occasion aberrancies of feeling, and so of will and action. I italicize "may" so as to intimate that this *need* not be the case; high, ethical feeling has even been noted in connection with severe intelligence defect.^c

Finally, both defective intelligence and psychopathy may occur in the same individual.[†]

Let us return to the first group of factors—that of the intelligence constituents—and the special problem of this report. Various synthetic interpretations of intelligence have been attempted in the form of definitions. Thus Ebbinghaus^a said that intelligence was combinational ability (*kombinationsgabe*); Stern,^b that it consists in "the general ability or capacity of an individual consciously to focus his thinking on new requirements; it is general mental adaptability to new problems and conditions of life"; Meumann,^c that it depended upon the capability of independent and productive thinking. He adds, "The more the ability evidences itself in our scholars (children) for synthetic thinking, for a systematic grasp of impressions or of acquired knowledge, the more intelligent do they appear, and indeed both their school attainments and the results of psychological ex-

*As we are speaking of psychopathy we have reactions in mind that are pathological in intensity or in the constancy with which they persist or recur. But it must be remembered that overamplitudes of normal reactions occur at times in normal individuals. These overamplitudes are then equal to pathological reactions.

†In the French literature, the Dégénérés (*i.e.* psychopathic constitutions) who have intelligence defect are termed "Dégénérés Inférieures"; those without defect "Dégénérés Supérieures." In the psychiatry of Ziehen, the psychoses are divided into such "with defect" (meaning intelligence defect) and those "without defect."

periments tallying in this; De Sanctis,¹⁰ that it consists in ability to judge, conceive, and reason—all involving abstraction and generalization; Warren,¹¹ that it means “‘fit’ reaction to environmental situations whether perceived or pictured”; Wundt,¹² that it is a combination of phantasie and understanding abilities (*Verstandesfähigkeiten*); Treves and Saffiotti,¹³ that it “consists in the greater or lesser ability of an individual to utilize the theoretical and practical worth of his ideas and acts in orienting and adapting himself to his environment by discerning that which is most advantageous for himself”; Binet¹⁴ that it “emphasizes three characteristics of the thought process—(1) its tendency to take and maintain a definite direction, (2) the capacity to make adaptations for the purpose of attaining a desired end, and (3) the power of autocriticism”; and finally Ziehen,¹⁵ that it is “essentially composed of memory, comprehension, and judgment or combinational ability.”

These definitions, however, with exception of the last, though interesting in showing that there are really no fundamental differences in the various opinions of what intelligence actually is, and though valuable as epitomizers in passing, scarcely serve the physician as working bases and in such synthetic forms interpret nothing and lend no insight into *pathology*, and not a clue to procedure where diagnosis is necessary or a therapy essential. Our science—all science—is superposed on analysis and on understanding of function, not through metaphysical intuition, but through comprehension of *parts* and their relations and interaction.

Just here, however, we get the usual interjection of the Binetist that intelligence cannot be crumpled into parts—that it is an entity, a biological indivisible *capacity*—not built up of functions or faculties (and once more the spooks of old “facultative psychology” are roused), and not examinable in fractions. Even Terman¹⁶ tells us that Binet succeeded where others failed (? !) because he got away from the old “structural” psychology method and laid hold of the *general level* of intelligence outright. “Binet’s psychology is dynamic. He conceives intelligence as the sum total of the thought processes which consist in mental adaptation”—and this is not explicable in terms of “faculties,” and the separate processes not accurately distinguishable.

If this were true, we as physicians would be compelled to eschew this method (of diagnosing generally without first estimating elemental parts) as highbrowism utterly unsuitable for our practice, for as we a moment ago owned—and this will be reiterated throughout this study—our method is that of analysis and segmentation. Only in this way do we grasp function—whether of the body as a whole, or the heart, kidney, a limb, or a joint. And to say one must fail to conceive the function because one tackles the thing anatomically or anato-physiologically is to aver the rankest absurdity. But not only is the point at issue untrue for the physician, it is just as untrue for the pedagogue¹⁷ and for the psychologist himself. Indeed, discussing this very problem, Ebbinghaus¹⁸ said:

In as far as these assertions concern the nature of mind (that it is a living totality and that the parts into which we analyze it have no real existence) they are unrestrictedly correct. The inferences, however,

deduced from this (that it cannot be split up and studied in parts) rest on a misunderstanding. A richly organized and intricate entity cannot as such be adequately represented at all or perspicuously described. One might contrive, howsoever one pleases, in order to acquire knowledge from or impart knowledge of it, one must resolve it into parts, otherwise for sheer totality one cannot discern the richness of its makeup. Only after one has viewed and considered the elements from different angles is it possible to construct a living notion of the whole, in which entity the latter, of course, alone has reality. There is indeed no other way whatever in which this entire encompassing and penetrant totality aspect can be methodically represented nor any other art of expression by which it can be simply communicated.

* * * * *

When the anatomist speaks of cells, muscle fibers, corpuscles, digestive organs, etc., as being parts of the organism, no one will misunderstand him to imply thereby that the individual is composed of an extrinsic aggregate of these elements, or that in the beginning the parts were present and that the organism was thereupon constructed from these parts, as a house from beams and stones. One also permits the physiologist to speak of circulation, breathing, metabolism, one after the other, as being various functions of the body; but one will not impute from this that he means these functions operate separately and independently in the sequence he enumerates them.

If one will only meet the psychologist on the same logical ground, the objection to the fractioning method will disappear.*

We may safely, therefore, ignore this criticism of the Binetist and proceed.

Raveling, then, the mental process involved in intelligence, we find something like the following: Consequent upon external stimulation we perceive, and the perceptions, if attended long enough, are cortically infixed—remembered. Where the attention does not hold nothing is retained (that is, not with any definiteness or clearness—not in a usable way).¹⁹ The things (perceptions) remembered are registered in association with other simultaneously perceived things (and in relation to time and place), and are furthermore bundled up—associated—in the brain with things of like kind already there. Nothing, in fact, is deposited isolated in our minds; always something is added to something else—and in such a way that things (concepts, ideas) belonging together are in some manner of means interrelated.¹⁹ This aggregate of memory-deposits comprises our *knowledge*. It increases as we grow older and naturally varies in different people. But as children for the most part are trained along similar lines, their knowledge is much the same and is augmented year by year at about the same speed.²⁰ Memory, however, not only implies the storing up of facts, but

*In connection with the consistency of this fractioning method, see also J. Schrenk’s most interesting and thorough study of schoolchildren’s ability to understand pictures. Schrenk concludes that the understanding of a picture cannot be considered a function as such nor examined as a uniform function, and that the *stages* in the development of such understanding set up as criterion of intelligence at definite ages did not, therefore, hold good, for such understanding had to be probed in terms of part-functions. His studies showed that certain part-functions develop at a different tempo from others and come to maturity at different ages. There were *stages*, therefore, for the part-functions, but not for picture understanding as a whole. He employed two very simple pictures and put forty-two test questions to each child. Über das Verständnis für bildliche Darstellungen bei Schulkindern. Wissens. Beiträge z. Pädog. u. Psychol., Heft 5, Leipzig, 1914.

the ability to hold them, and also to recall and reproduce. The better the mental arrangement of the matter the richer (and stronger) the associations, the better the recall.

In the process of sizing up and ordering the new incoming matter, the knowledge already possessed is exercised. The new is compared with former mental pictures, the precise patterns collated and contrasted. This takes place even in the very young child. As it grows older it not only compares grossly, it distinguishes parts from out the whole (as sweetness and whiteness of sugar) and compares these and also binds parts into larger complexes (as rain, lightning, and thunder into the concept storm) or, again, spies similarities in large numbers of varied objects, and so generalizes and later abstracts. This is the procedure we term *comprehension* or *understanding*. It is evident enough that the greater our knowledge the better of course our comprehension. On the other hand, through differentiating and remembering differences our knowledge grows.

Lastly—and this is the highest of our functions and matures late in the child—we are able to unloose associations already registered in mind, or break up concepts into parts and recombine them in new ways—even into relatively quite new forms. This is termed *combination*. Through this ability we can supply a fitting completion where but a part is given in a train of thought, or we span gaps where links are missing. Thus we orient ourselves in time and place, adequately meet new situations, bring about logical synthesis in our thinking, discern meaning and motive in the composite of picture, story, and action, sift cause and effect, exercise critique, judge and show judgment—and finally imagine, compose, and create.

Such is the intelligence *process*. It is found crystallized in Ziehen's simple definition. It is the substance of the conception of most of the authors, only one or other gives it in lesser or greater detail and one or other lays more or less stress here or there. But this process or functioning that we have itemized into several paragraphs, however interwoven and "entitized" in actual reality, must, when studied and investigated, be studied and investigated *in detail*.

Some authors (as noticed in several of our definitions) seek a teleological motive in intelligence, and thus require appropriateness or practicality or a fitness of reaction to the environment for their criterion of the matter. Such teleological motive, however, need not be separately considered, as the psychological functions with which fitness, practicality, etc., are attained are enumerated among the factors given above.²²

Two other mental *circumstances*, however, might be noted while we are still at this point of our study. The first is an *intensity* in the mind's activity which, though not a part of the intelligence as such, influences it decidedly. This may be a general metabolism phenomenon or more probably one of internal secretion. When its potency is low the mind is slow, difficult, laboring. Some children because of this straggle behind others of their age. They are not defective, but deficient. Thyroid sometimes whips up such brains to keener activity. Where the potency is high the individual is sharp, alert, quick, etc.

The second is that of mental *cohesion*. Even the layman speaks of "keeping one's wits together." There are individuals in whom the intelligence interplay is easily disequilibrated (instability in the long association fibers?)—through shyness, fear, "stage fright," stress, the unusual, nervousness of any cause, etc. The

vegetative system is frequently involved at the same time and such persons perspire, flush, or pale, have palpitation or vertigo, etc. The attention becomes "dispersed," and is either uncontrollable or only with great difficulty. Such individuals may be quite normal or even exceptionally intelligent, but show up badly on all tests, anything demanded of them before other people or in public—i.e. in the limelight. This abnormality in mental cohesion either belongs to psychopathy or is occasioned by it. Both phenomena may be hereditary—run in families—or occasionally noticed after illness.

Returning to our methods of examining intelligence, the second one noted, that of probing the various faculties or functions singly, is seen, in consideration of the above, to possess the requisites for a proper diagnostic method in contradistinction to Binet's in which a general average or totality quotient is directly sought. It is the method that fits in with medical procedure and science generally and lends itself, as we shall see, to the vicissitudes of pathology. On the other hand, it has defects, and one so grave as to annul all our praise if this cannot be overcome—namely, the lack of age norms, the very thing so conspicuous in Binet's work. Thus in testing comprehension or combination, for instance, it might continually be asked are the questions suitable for this or that age, are they not too easy or too difficult? This is the great shortcoming of the method. A lesser defect is its lack of system, there being no regular procedure and no uniform graphic evaluation.

This general criticism also applies to the single-test methods already mentioned—with the exception of Ebbinghaus' completion and Mikulski's picture test, both of which can be graphically evaluated. The age factor, however, is not considered in these.

Rossolimo's "profile," to which we shall return further on, evolved on the basis of the facultative test method, introduces an elaborate system of procedure and a quantitative evaluation (i.e. the "profile"), which may also be numerically expressed, but lacks the age factor. Three main groups of "psychic processes" are examined: A, attention and will; B, perception and memory; C, associative processes. All in all, nine processes are taken up (more exactly speaking, eleven), attention, will, perception, optical memory, memory for speech, for numbers, comprehension, combination, resourcefulness (mechanical sense), completion or imagination and observability. These are again subdivided so that the processes and subprocesses number thirty-eight, and each of these is examined with ten tests (380 tests in all, therefore). The quality of the tests is very uneven, there being some good and some very poor tests. One needs a tachistoscope and many charts of figures and designs and pictures to carry out this method. There are other objections, too, but these cannot be gone into here. That much, however, can be learned from this "profile" is taken up further on.

The point-scale method of Yerkes has some advantage (and elasticity) over the Binet method (though most of the Binet tests are used), escaping the "all or none" scoring, and admitting the age factor by computation of points. The facultative division is as completely missing as with Binet. Each test is "weighted" with "points," the enweightment varying with different tests. W. F. Dearborn²³ has recently proclaimed this weighting as purely arbitrary, asking, for instance, why (in response to the Binet picture) one point is credited for enumeration, two for description, three for interpretation, etc. A footnote of Dearborn's is interesting as an eye-opener to "statistics" as we get them these days. It reads: "Note the remarkable conclusions of M. T. Wolley with the point-scale as to the 'startlingly high' percentage of feeble-mindedness in eighteen-year-old industrial workers—40.5 per cent. of boys and 42.5 per cent. of girls, or by a more conservative standard 25.5 per cent."²⁴ As to the worthlessness of many of our psychoclinical "statistics," see our comment further on.

The Binet Method.—Vis-à-vis this facultative test series, Binet's, which pivots wholly on the age factor, the very thing so seriously missing from the former, looms up at first sight like a happy find. Better acquaintance, however, brings out several faults, two of which prove such immense drawbacks that the method becomes quite useless for the physician—and inutile enough for the pedagogue, I should judge, if these faults are admitted—the one being the failure to keep psychopathy in mind, the other the insistence on a *general age average*, that is, an averaging of the mental normality or abnormality (pathology), a thing that cannot rationally be done and which would be of little use for us in our profession if it could.

If, for instance, one looks over the tests employed by Binet one notices that they for the most part involve language efficiency,²⁵ and the knowledge of school trained facts. It just happens, however, that the largest class of cases coming to neurologist, psychiatrist, and courts (in whom an intelligence examination becomes an issue) are types of individuals designated "psychopathic constitutions," i.e. who evidence abnormal thought tendencies and trends, and these are deficient in school-trained ability because they shirk school or are truants, run-away children, or unmanageables, in short, individuals who spend little or no time in school and are unable to pay attention even when they do go. Yet careful study by Ziehen²⁶ and Stelzner²⁷ showed that such children might have quite normal intelligence. Still later F. Cramer²⁸ came to the same conclusions in connection with the examination of delinquent and criminal children. Such psychopathic trends, therefore, prove important levers in the mechanism of mind play and their presence or absence makes the profoundest difference when it comes to evaluating the intelligence performance. Yet Binet takes no cognizance of psychopathy.*

And as for language efficiency in itself, when one considers from what generally poor or at times even degenerate homes, such children often come, and that they copy the talk of the home and in large measure miss the correcting and developing influence of school, teacher, etc., one scarcely wonders that this efficiency is meager indeed.

The fact that the Binet testers have in so heedless a fashion splurged on without considering these abnormal character trends and impellents has introduced a spurious element into the entire test performance as a result of which the statistics, "curves and correlations" given us in such abundances by those "testing for feeble-mindedness" among institutional delinquents, among inmates of prisons, reformatories, etc., are most unreliable. And the constant citation of these figures only helps to obscure the issue.

In Terman's book, for instance (l.c. p. 8), one finds an entire page of such statistics. Here we read that Miss R. tested 100 girls of the Ohio State Reformatory and found 36 per cent. certainly feeble-minded. G. tested 100 juvenile court cases, chosen at random in Newark (!), and classified nearly half as feeble-minded. Of fifty-six delinquent girls between fourteen and twenty years of age, H. and G. found almost half to belong to the nine or ten year level. Miss D. found 28 per cent. subnormal at Lancaster. At the Joliet Prison, Illinois, Drs. G. and L. E. O. found 50 per cent. of the female prisoners

feeble-minded and 26 per cent. of the male prisoners, etc., etc.

The same sort of statistics were given in a dozen studies on delinquency at the meeting of the American Psychological Association a year ago. The method of acquiring these statistics was readily enough perceived in these papers. The Binet testing hysteria has written the word *feeble-mindedness* so large in the minds of all "testers" that nothing else is seen or sought for. One would almost think there was no other mental abnormality but feeble-mindedness. And if these examiners knew of any other causes of delinquency than feeble-mindedness they surely did not divulge the fact in their papers, for the word psychopathology was not mentioned and diagnosis had but one single meaning—something got to with Binet tests!²⁹ And yet it seems the consensus of opinion among Continental authors (among whom the Binet hysteria has haply not broken out) that feeble-mindedness has in itself nothing to do with delinquency, that psychopathy, environment, suggestion, poverty, etc., are the preponderant causes.³⁰

Terman also writes of the "stigmata" which Lombroso thought to be earmarks of criminality, as being rather the physical accompaniments of feeble-mindedness, and that "they have no diagnostic significance except in so far as they are indications of mental deficiency." This is as startlingly misleading as the above. There are stigmata of syphilis, of rickets, and so-called stigmata of degeneracy (more properly termed stigmata of hereditary taint). These latter occur singly here and there in normal individuals. They are more frequent in psychopathic constitutions, and especially in certain individuals who have a severe psychopathic or convergently psychopathic heredity ("degenerative psychopathic constitution"). But these stigmata have no connection with feeble-mindedness, though they may be found in such cases that are feeble-minded through vicious hereditary strain. Finally, they have been found even numerous in individuals who have little or no mental abnormality, and again they are often wanting in individuals who are most abjectly psychopathic.³¹

Similar criticism is applicable to studies of so-called "degenerate" family trees prepared by lay workers. In these the factors of heredity are badly muddled, and as for differential diagnosis, no thought is given to psychopathy, lack of schooling, bad environment, and execrable example. Whenever there is an apparent lack of knowledge feeble-mindedness is assumed. In several such studies I have seen, as well as in papers relating to feeble-mindedness, one constantly hears of the feeble-minded procreating feeble-minded—as if feeble-mindedness were hereditary.³² Do the authors get their facts from the above statistics? On this very point I have been able to find very little indeed that was reliable in the literature.³³

The second great drawback of the Binet method, mentioned above, is probably the superlative objection to its acceptance in medical science, namely, the evaluating of intelligence through an equation of the general ability. That such an averaging is possible with Binet tests is most improbable. But let us for the moment assume that this is so; of what value then is this equation to the diagnostician or therapist (or even the remedial pedagogue)? If the general ability is below the normal what are we told of the abnormal condition? *Is not that what we are specifically after?* It occurs but rarely if ever in medical science that one diagnostically appraises the amount of health remaining; one seeks to survey the abnormality, to estimate the disease process, and one accomplishes this through scrutiny of the parts, not the whole, of the organs separately, even the various elements of each organ. If a kidney is diseased, the urine is analyzed—and microscopically examined—and through the findings one determines the nature of the pathological condition obtaining. There are but a half dozen types of kidney abnormality, and

*Wishes in fact to exclude such cases from his problem. See *L'Année psychol.*, 1905, XI, p. 191, etc.

scores of different types of brain disorder. Are we to disregard the fact? Are we blindly to accept a patently false hypothesis to the effect that abnormality of mind is always one and the same, namely, *defect*, and that this is to be measured in quantitative gradations from a supposed norm (hence the everlasting "idiot, imbecile, or moron!") and furthermore that this defectivity is a homogeneous thing affecting the mind generally, like a saturation? The Binetist does, and because of it a decade of Binet testing has added not a whit to our knowledge of mental pathology, diagnosis, or therapy.

We must consider this supposed *generalization* of abnormality more carefully, for the whole Binet problem stands or falls with the truth or error of the matter. Few will assert that normal brains mature *generally* or have average abilities. Even the layman is aware that individuals excel in certain abilities and are lacking in others. And who does not know people in whom the most exceptional excellence is found alongside of general mediocrity? In this connection Meumann,³⁴ the foremost of pedagogues, emphasizes the fact that not only in adults, but especially in the intelligence examination of children does one find this great difference in abilities (*grosse leistungsdifferenzen*), high efficiency of performance in some subjects, low efficiency in others. Nor does the progress in various subjects throughout the school years go by general average; it is up here, down there, at a level elsewhere. Upon this important fact was based the suggestion of Raschke at the Dresden Pedagogical Congress of 1911 (*l.c.*) for a school system composed of norm-, sub- and super-classes, each child going for instruction in this or that subject to the class corresponding to his normal, subnormal, or supernormal ability in that particular subject.

So much for normality. Now, how about abnormality? Seashore objected to this mean evaluation got by the Binet tests on the ground that retardation does not follow a common flat level any more than growth does, and that a child could be at the mental age of six in one capacity and 12 in another.³⁵ In the matter of psychopathology, as we clinically are acquainted with it, *general* impairment or inefficiency is not come upon save possibly in very far gone states or in abject aments in whom differentiation, therapy, or aught else is profitless. As regards the majority of disease processes they involve the brain *electively*, and in a most astonishing way.³⁶ Let me only refer to the Korsakoff syndrome, malarial amnesia, the aphasias, congenital alexia, and other congenital aphasic forms,³⁷ and paresis.³⁸ It is similar with drugs and poisons; so characteristic is often their election that we differentially diagnose the conditions of poisoning from the typical clinical "picture." Again, and this is decidedly interesting, v. Monakow in his *Diaschisis* studies³⁹ claims this same *election* not only in the matter of actual traumata affecting the brain, but of *psychic insults* as well (as typical paralyses or blindness or speechlessness in hysteria).

Finally, let me say an additional word about Rossolimo's *profile* as this author's work has not yet been aired in our literature,⁴⁰ and his contention fits in so ideally with these claims momentarily under discussion. Rossolimo, as already mentioned,

chose eleven mental processes as functions of intelligence and again subdivided these so as to have 38 part-functions to test, applying ten tests to each. On his *résumé* sheet he placed these headings one under the other and on the line for each rubriced ten spaces (corresponding to ten tests). If but six tests were passed, a mark was made in the sixth space; if on the next line eight were passed the mark was placed in the eighth space, etc. At the close of examination a line was drawn from mark to mark down the page.

And what did the result on normals and abnormals show? A straight line down the page? Why, no, not even a wobbly "almost straight" line, but a very irregular zigzaz, with zigzags differing in different persons, and especially—and *this is really important*—a definite, almost characteristic zigzag repeatedly showing itself in the various clinical entities. This zigzag line is what Rossolimo terms the *profile*.

Rossolimo examined not only normals, but retarded and defective children, such as were lazy, and such as had dispersed attention (*Zerstreute*), furthermore, cases of paresis, early and late stages, cerebral lues before and after treatment, arteriosclerotic dementia, chronic alcoholism, Korsakoff cases, traumatic neuroses, etc. In all the *profile* was distinct and rather *characteristic*.

Condensed such a profile would look as follows:

Average profile of traumatic neurosis.

Much else can be learned from Rossolimo's studies, but we haven't space for further details at present. His *profile*, however, must be remembered as a decidedly important substantiation of our premise, and as showing up the Binet error, as it were, in splendid *bas relief*.

Is this evidence enough? If so, we must emphatically insist that the examiner approach his task not with a quill, a thimble full of psychology, and a Binet sheet, not with a vision obscured by an hypertrophied feeble-mindedness notion, but with the broad conception that pathological processes are manifold and that when they affect the brain, and so the mind, whether because of hereditary or congenital factors, natal accidents, disease aberrancies whether engenic, or exotic, poisonings, intoxications, autointoxications, or traumata actual or psychic, (for these are the causes of abnormal mind), they do not make themselves manifest in a general way, but are variously, often

characteristically, selective. *And the fundamentals of our knowledge of neuro- and psychopathology are nothing more but the knowledge of these differentials.*

This issue cannot be magnified and indeliberized enough in the minds of physicians—this necessity of *differentiation* and a spacious background knowledge of pathology. It was this very lesson that Kraepelin brought out with such trenchant emphasis in his report on the psychological methods of examination at the Stuttgart Congress in 1911. All that we have learned of psychopathology has been learned in this way, he said, and to advance further this is the only method of choice—to divide, subdivide, and scrutinize, and ultimately balance up the dissimilarities of our findings.

Let us repeat, then, to progress we need finer differentiations, not generalizations, and any method of mental examination of abnormals—or even normals, as we have seen—that neglects this fact is a mockery of science as ours is plied to-day and from this viewpoint must be labeled worthless.

Some of the minor objections to the Binet scale are also important enough to merit special mention. To get an accurate range of an individual's mental standing with five questions is scarcely logical.* Any elasticity of adaptation is also precluded by so brief an examination. The paucity of the tests, then, is a real objection.

Again, looking over the groups of questions allotted to each pedagogical year, one finds that the functions tested in one year (memory or comprehension, for instance) are not the same as are tested by the questions allotted to the succeeding year, etc. Therefore, one cannot truthfully say one child tests a year in advance of another for you have not tested the same functions in each. This, for Meumann, was one of the greatest failings of the Binet method¹

In conclusion of our criticism of Binet, let us return to his *psychologist* devotees and point out something that belongs to the hysteria of the movement rather than to Binet. It is pathetic to hear the professional tester speak of this scale, as if it were something hallowed and its gage as stable as a yardstick. Thus the term "standardization" has come into use, these tests being "standardized"—and hence all others scabs. Yet how much actual backbone is there in this standardization? Binet himself, I believe, said it depends much upon the person making the test what the results will be, for he must judge the responses, and with a different examiner the results may be different. I noticed this so frequently some years ago that I even had the suspicion some examiners unconsciously size up a child and assume about what its pedagogical age should be and make the test-outcome approximate this.

The questionability of standardization is raised in still other ways. Binet applied his tests to the children of the poorer districts of Paris. His pedagogical age-average was based on these results. He found that the children of better schools graded one and one-half years higher (in one-quarter, even 4 or 5 years higher!). Decroly and Degand² in Brussels and Jeronutti³ in Rome found

*In Rossolimo's method 380 tests are put! while Schwenk gives 42 questions to bring out picture understanding alone.

that the children they examined tested almost two years in advance of the Paris norms, while Shubert⁴ at Moscow found that the children of that city tested, reversely, two years behind. Because of these results Meumann thought the Binet tests must, if anything, be *milieu* tests. Have we taken these facts into consideration when testing our own mixed population? Is one to make allowances for race, place, training?

The problem looked at from still another angle engenders the same doubt. If one goes over the "Binet sheets" used at Johns Hopkins, at Ann Arbor, such as seen in New York and elsewhere, one notices differences—certain questions being omitted, others placed at different age levels. One asks how or why is it done? How account for the move if each is "standardized?" (And one must bear in mind the considerable variation in the end results of evaluation when one or two shifts are made in a set of five or six questions.) And then compare these sheets with the Terman revision and additions (made in the right direction, I think) and note the decided changes!*. Add to this the very sound criticism meted to certain Binet tests by Bobertag⁵ and the changes which Meumann himself suggests at the end of his second volume, to say nothing of the individual testers' choice between the 1908 and 1911 revisions of Binet, or Goddard's form, some choosing one, others the other, or partly the tests of one and partly of the other,—and one begins to believe that if anything of exact standardization is left it is the opinion of certain enthusiasts for this method and their results.

How far we still are from accurate standardization may be surmised when we look over such studies as J. van der Torren's, who tried out the Heilbronner picture test on 180 children and found remarkable difference between the sexes, the boys being superior to the girls at all ages, the superiority increasing as the age level rose. Even at twelve the girls were only at the level of seven-year-old boys, a difference of five years! (J. van der Torren, "Über das Auffassungs- u. Unterscheidungsvermögen f. optische Bilder bei Kindern," *Z. f. Ang. Ps.*, I, 1908, p. 189, etc.). Are there such sex differences in other tests? Bobertag, for instance, noted a difference in connection with knowledge of colors, while Yerkes and Bridges also mention sex differences, especially between the ages of five and seven, writing that they "suspect that at certain ages serious injustice will be done to individuals by evaluating their scores in the light of norms which do not take account of sex differences" (*l. c.* p. 73). Bloch and Preiss on the other hand found differences at the ages of 8, 9 and 10, in their tryout of the B. S. tests, and in fact, in all the tests excepting three, showed the boys to give a far higher percentage of correct answers, *often double as high!* (*Z. Ang. Ps.* 6, 1912, pp. 539-547). Differences were also found by Torren in the observability of country and city children. (Ziehen also mentioned such a difference in connection with defining tests.) How shall we work these facts into the standardization scheme? How, besides, shall we account for the divergence of results of examiners in such tests as giving sixty words in three minutes, which one places in the tenth year, others in the fifteenth?

Furthermore, how shall we handle the difference between the lower and higher classes, the cultured and the uncultured? Binet found as much as one and a half years' difference between them. Both Bobertag and Gaupp noted differences in individual tests. Rossolimo in several of his series offered separate tests for cultured and uncultured, respectively. Then, too, we have among our normal children of every age, average, above

*I have heard orthodox Binetists strongly depreciate these changes. "Terman's method wasn't 'biological' as B.'s is," I was told—whatever that might mean.

and below average groups. How shall we work this into our tests? Treves and Saffioti (*l.c.*) arranged the Binet tests for three such divisions at each age, for weak, average and good—asking not five tests, however, but fifteen of the weak, twenty-two of the average, and twenty-nine of the good (at the age of six; at eight, nineteen, twenty-nine, and thirty-six tests, etc.).

Nor have we by any means as yet solved the problem of test values—the comparative value of tests—or how to use these values in reckoning our coefficients. Shall we call all tests equal, as Binet or Terman does, or shall we allow greater “function-value” or “diagnostic-value” to some tests, or deem some more really “intelligence tests” in contradistinction to such as are more decidedly school; psychological, or *milieu* tests? (Meumann, for instance, has arranged his tests into divisions of “Developmental, Endowment [Begabung], and Environment tests.”) And shall the better or the more really intelligence-tests be “weighted” and count more in the final evaluation? Stern (*l.c.*, p. 65), for instance, brings up the following: “Take two tests, a and b, both passed by 75 per cent. of the children at the age of nine, but when also given to the eight and ten year olds are passed thus: a, by 65 per cent. at eight and 80 per cent. at ten; b, by 45 per cent. at eight and 90 per cent. at ten. These two tests, though standardized for the ninth year, are nevertheless very different in their values.” Bobertag was the first to notice this and stated that such tests are the more valuable which show the greatest advance between successive ages. Test b, here, is therefore the more important.

Stern (*l.c.*, p. 74) also alludes to this difficulty in summing up: “If a child passes all the six-year-old-tests, two of the seventh year, three of the ninth and two of the tenth, and another who likewise passes all of the sixth, passes also three of the seventh, five of the eighth, and two of the ninth, but none of the tenth—each totaling two years’ additional credit according to Binet—shall we count the children equal or shall greater credit be given the child passing the two ten-year tests?”

Finally, shall we give part credit for tests partially passed, or must it be “all-or-none”? and shall we require one correct of two trials to pass, or 2 of 3, or 3 of 5, or, indeed, the majority of longer series—let’s say ten? (all of which methods appear to be in use at present).

When one considers the obviousness of the strictures thus far arrayed against the Binet method one is not only astonished and exasperated at the Binet invasion of our clinics and the lay appropriation of this field of work so decidedly a medical matter,* but mortified at the gullibility of our own profession that in so many instances has accepted these half-baked facts as bona fide data and given its votaries carte blanche to plunge ahead and with surpluse of assurance take possession of the place. In this connection W. B. Cornell, director of the New York City Children’s Hospital and School, has recently written:†

“In other words, we have a lay person examining diseased or abnormal mental states, and making diagnoses thereon. This is quite a departure from the legitimate field of psychology, so much so that these testers themselves appreciate it and have called themselves clinical psychologists. So self-satisfied have some members of this new hybrid genus become that, clinging to the Binet scale as a fetish, they have grown intolerant and have declared that no one shall use the scale except the *delecti*, and many of these self-anointed. In one of the mental clinics of New York the psychologist went to the medical director in great

*By which I do not mean to say that we cannot advantageously employ the nonmedical psychologist in our clinics and be greatly aided through their help. I have always had and very greatly appreciated this assistance. The *psychologet* and the *psychologet* movement, however, is to be strongly decried as a menace and a nuisance. But even here the fault is not theirs, but decidedly and entirely ours.

indignation because one of the physicians of the clinic had dared to use the Binet scale on a patient. The sanctum of the clinical psychologist had been violated! In some cities, particularly in New York, these clinical psychologists have private practices, are carrying on treatments, and it almost seems as if we would soon have a new cult, if indeed such is not already established. Many of the psychologists are doctors of philosophy, and they dearly love to be called ‘doctor’ on all occasions, and especially to be taken for doctors of medicine. Personally, I see no excuse or reason for calling anyone with the Ph.D. degree ‘doctor.’ If so, to be consistent, why not call the M.A.’s ‘master’ and the B.A.’s ‘bachelor,’ etc.? As long as the term ‘doctor’ is commonly used to indicate a person who treats diseased conditions with medicinal or surgical measures, we should avoid its use as a title for others not so engaged.

“As a rule, the ‘clinical psychologist’ is not concerned with the causes of feeble-mindedness. The whole matter is very simple! The scale is applied, the child is feeble-minded—and should be segregated—nothing easier!”

Looking over the ground covered we must admit, then, that the methods of examining the intelligence are wholly inadequate—for the purpose of diagnosis and therapy, in fact, almost useless. Is there not some way, we must ask ourselves, out of the quandary? Is there not at least a clue given in the methods considered which may, if followed up, eventually lead to a dependable procedure, rational and effective? We believe we have such a clue—and that we are sharp on its track.

It is now almost a decade ago since we inaugurated a “psychological room” at the Vanderbilt Clinic, College of Physicians and Surgeons (in the Department of Applied Therapy; three years ago taken over by the Department of Neurology) for psychological examination and therapy.* From the earliest, our intelligence examinations seemed unsatisfactory and little by little it dawned upon us that the positive elements of the various methods might somehow be combined and the negative elements thus eliminated. In this way the following scheme of procedure was evolved.

The intelligence *factors* were arranged on a “sheet” in a definite and systematized manner, factors and sub-factors, the purpose being to test every examinee in each. Not only were a sufficient number of questions given, but the arrangement allowed of the addition of still further tests when this seemed advisable (when there was doubt as to the results). Furthermore, both simple tests were presented and composite tests entailing various factors in combination. The age issue, neglected in all but the Binet method, was also introduced, each test given being approximately appropriate for a special pedagogical age.

The tests employed were not haphazard tests, but for the most part the more reliable of the tests of Ziehen, Binet, Meumann, De Sanctis, Rossolimo, and others, beside several that we ourselves have found applicable and trustworthy. In the present presentation several of the tests formerly employed have been dropped, and tests of Terman, Weigant, and others of our own added. In order to determine norms of age, the results of the findings of Binet, Bobertag, Terman, and Meumann were compared, as well as data gathered by Ziehen, Gaupp, and other writers, and finally our own try-outs of series of tests at certain

*This was possibly the first modern *psychological clinic* started in America.

schools. From these collations and studies it is found that many tests may safely be used as indices of intelligence (or special factors of intelligence) of a given pedagogical age. On the other hand, there are many tests for which, despite all talk of standardization, nothing positive has been determined and which cannot be used in a definite way to gage the intelligence of a specified year. It is not certain whether the test applies only to the year in question, or *also* to the next, or indeed *only* to the next. In such cases I have indicated the fact by putting the number of both ages in brackets after the test. Sometimes the uncertainty involves not only two but even three or more years.

In our "intelligence sheet" previously published the tests were awkwardly grouped, all the tests of knowledge, for instance (the tests for all the years) listed under Knowledge, those for memory under Memory, etc. This has been entirely changed. In the form now presented each year is taken separately and all the tests of the various functions to be tested are arranged under the caption of that particular year.*

The following is the test sheet for the sixth year, and this must suffice for the present to give an idea of the general scheme, our paper having grown too long to include all the tests for all the years with copies of the pictures and apparatus used. A complete review of all the tests and a detailed account as to their application will be reserved for a separate communication.

TESTS AT THE AGE OF SIX.†

Name:	Clinical diagnosis:
Age:	Psychological diagnosis:
School grade:	retarded years.
Senses: S. H. T. S.	Physical status:
Speech:	Mental attitude:
Sensory-motor:	Neuro-Psychopathy:
Understanding:	School report:
Agility, dexterity:	
Mechanical sense:	

1. Knowledge:

- (a) Things in a room: Chair, table, sofa, bed, picture, lamp.
(Point to, or show pictures of, or a picture in which all may be found.)
- (b) Things on the table: Knife, fork, spoon, plate, cup.
- (c) Things on the street: House, store, wagon, taxi; car, policeman, soldier, engines, trains, garden, flowers. (6-7.)
- (d) Animals: Horse, dog, cat, cow, sheep, pig, birds, fish.
- (e) Summer, winter, spring, fall, Christmas. (6-7.)
(Ask "When does the snow fall?" "the grass grow?" etc.)
- (f) Colors: Names R., B., G., Y. (5-6-7.)
Recognizes R., B., G., Y., W., Blk. (4-6.)
Go., Si., Br., Gr., V., P., Or. (5-6.)

2. Memory:

- I. Send child on make-believe errand to store for three things at 5, 15, and 8 cents.
- (a) II. Repeats four to five digits.
- (b) III. Recalls purchases under I.
- [(c) Recalls colors as at 5.]
- [(d) Remembers forms of wheel, box, top, stamp, coin, ball, chimney. (Use cardboard upon which variously shaped silhouettes are pasted.)]

*Possibly the arrangement of three years on one sheet will prove best in the end, thus the ages of 6-7-8, 9-10-11, 12-13-14.

†Our test sheets are procurable from the Fetzer Press, 62 Reade Street, New York; the pictures used, from J. T. Beals, 71 West Twenty-third Street, New York City.

- (e) Copies a triangle.
- (f) Repeats (14 to 18 syl.): "Let us all go for a walk in the park this afternoon." (14 syl.)
"How would you both like to go to the country for a picnic tomorrow?" (18 syl.)
(Note (I) No. of syl. (II) No. of sensible or senseless errors.)
- (g) Carries out three commissions. (5-6.)
3. Comprehension:
 - (a) Numbers: Counts 13 pennies or stones. (6-7.)
 - (b) Defines (per usage): Same as at 5.
(Fork, chair, pencil, cake, doll, wagon, horse, soldier, penny, rose.)
 - (c) Forms: Balls, cubes, pyramids, cones, parallelepipeds.
 - (d) Relations: Larger, smaller; nearest, most distant. (6-7.)
 - (e) Divides line (of 2 cm.) into longer and shorter parts; in half. (6-7.)
 - (f) Directions: Right, left (6-7); front, back, above, below.
 - (g) Weights: Arranges more than 2 (3? 4?).
 - (h) Pictures: Describes. (6-7.)
(Ask "What is the picture all about, what is happening?")
4. Combination:
 - (a) Orientation:
 - Time: (Morning or afternoon [day], season.)
 - Place:
 - (b) Picture lacking eyes, nose, etc. (6-7.)
 - (c) Completion of part pictures (or recognition of the whole by part shown).
 - (d) Grasps situation of very simple pictures.
 1. Boy caught in the rain. 2. Wind blowing boy's hat away. 3. Boy skating, falling on the ice and crying.
 - (e) Ask in each case "What should he have done?" (6-7.)
5. Attention:
 - (a) Attention paid to things pointed out in the room; in the pictures shown.
 - (b) Sticks to tests.
6. Feeling:
 - (a) Esthetic choosing 1, 2, 3. (5-6.)
 - (b) Reaction to story told and pictures shown.

NOTES AND REFERENCES.

1. See the very interesting paper, "Psychology vs. Psychiatry, etc., in Diagnosing Feeble-mindedness," by William B. Cornell, *N. Y. State Jour. of Med.*, November, 1917, which brings up this point in particular.
2. Many prominent psychologists and pedagogues seem also to come to this conclusion in their own fields—Meumann, Stern, Yerkes, Thorndike, Gault, etc.
3. Other single tests are the color-naming test of Warburg, the Bourdon attention test, the part-picture test of Mikulski, the logical-synthesis and cue-story tests of Meumann (tests of the intelligence quality rather than quantity, or quality-quantity tests), the picture-series tests of Henneberg and Heilbronner, the completion tests of Masselon, Finckh, Ziehen, etc.
4. Rossolimo, G.: "Die psychologischen Profile," etc. *Klinik f. psych. und nervöse Krankheiten*, VI Bd. 3 Heft. p. 249; 4 Heft. p. 295, Halle, 1911.
5. This approximates the opinion of most of the authoritative writers on the subject, Ziehen, Binswanger, Sommer, Kraepelin, Meumann, Stern, Ebbinghaus, Bechterew, De Sanctis, etc., and of Binet himself. The precise divisions and subdivisions read somewhat differently in each, but amount to much the same thing. See text further on.
6. There are examiners who are prone to produce such motor disequilibrium in the individuals being tested. As I have pointed out elsewhere, such persons ought not to undertake this work. The methods used at cross-examination in court actually tend to produce this abnormal condition and must be looked upon as most objectionable.
7. See Hermann's study, "Das Moralische Fühlen und Begreifen bei Imbezillen und bei Kriminellen Degenerierten." *Juristisch-psychiatrische Grenzfragen*, Marhold, Halle Bd. 8, Heft 4/5, 1912, p. 61 et seq.

16. See, for instance, Meumann's "Experimentelle Pädagogik," 2d Ed., Vol. II, 13th Lecture, pp. 714, et seq.

17. Ebbinghaus, H.: "Grundzüge der Psychologie," Leipzig, 1911, 13th Ed., Vol. I, p. 177, et seq.

18. Abnormality of attention does not fall to the intelligence, but to psychopathy. In other words, attention is not a fundamental of intelligence. It may be most dispersive and erratic in a highly intelligent neurotic—and excellent in a very stupid or deficient individual. One finds, however, that attention becomes poorer and poorer as one descends the scale of feeble-mindedness. Sollier set up a classification of feeble-mindedness according to the amount of attention still possible, the severer forms being quite devoid of any ability to attend.

19. It should be remembered that we possess anatomical evidence of this. Parts of the cortex, it is believed, are occupied in perception or innervation (both these also possibly in retaining memories) parts only in storing memories—the *mnestic* fields (Exner, Ziehen, Nothnagel, Liepmann, etc.) All memories of vision are stored in one locality, of hearing in another locality, of motor speech innervations in another, etc. Within each of these localities short intracortical associations (fibers) occur—can be microscopically demonstrated. Between such various localities there are long association fibers, these dipping into the white substances. The further the localities are apart, the deeper these associating fibers run in the white substance. (v. Monakow, Liepmann, etc.)

20. Hence the feasibility of measuring knowledge in children according to an age-norm standard. This is not possible in adults. For a full and detailed discussion of these facts see our "The intelligence Examination and Evaluation," *The Psychological Review*, Vol. XXIII, Nos. 5 and 6, October and November, 1916.

21. The associations are made stronger through tonal feeling and repetition (practice—i.e. habit). But the *quality* of the brain tissue has much to do with it. In some individuals there is a greater, in others a lesser, native plasticity.

22. For a discussion of this, especially in connection with Stern's definition and its criticism, see Meumann, No. 16, Vol. II, pp. 718-719.

23. *The Psychological Bulletin*, Vol. XIV, No. 6, June, 1917, p. 224.

24. *The Survey*, November 4, 1916.

25. For a fuller criticism of this point see L. P. Ayres, *Psych. Clin.*, 1911, v.; Mehnert, Dresden Congress, 1911; Report, Teubner, Leipzig, 1912; our own study, "The Intelligence Examination and Evaluation," second report, *Psychol. Revue*, Vol. XXIII, No. 5, p. 338, etc., and E. L. Thorndike's "The Significance of the Binet-Simon Tests," *The Psychol. Clinic*, October 15, 1916.

26. Ziehen, Th.: "Die Erkennung der psychopathischen Konstitutionen," etc., S. Karger, Berlin, 1912.

27. Stelzner, H.: "Die Psychopathischen Konstitutionen," Karger, Berlin, 1911.

28. Kramer, F.: "Arbeiten des Bundes für Schulreform," Arbeiten 5, p. 23, etc., Teubner, Leipzig, 1912.

29. Even Goddard, who read a paper on "Fifty Delinquent Girls Tested with the Binet Scale," when asked, "How about the delinquents who are not feeble-minded?" answered that he couldn't say anything on that score, as his work was among the feeble-minded—or something to that effect.

30. Ziehen, Pondojeff, Bechterew, Scholz, Gruhle, Gaup, Cimbäl, Hermann, Fürstenheim, etc., etc.

In the above implication I do not, however, mean to say that feeble-mindedness is not a good *soil* for delinquency to grow on it; it is such a soil, yet not *the* soil, just one of many, and decidedly less fertile than environment, psychopathy, etc. On the other hand, Hermann pointed out that even the severest defectives may have a splendid moral makeup. *l. c.*, p. 61, etc.

31. For literature see Th. Ziehen's "Die Geisteskrankheiten des Kindesalters," 3 Heft., Berlin, 1906, p. 31, and literature there cited; also Bruns-Cramer-Ziehen, "Nervenkrankheiten im Kindesalter," Berlin, 1912, p. 24.

32. Only recently again such a statement was made in passing by J. L. Herrick, in an article in the *N. Y. S. Jour. of Med.*, November, 1917; and in a Report of the N. Y. Committee on Feeble-mindedness, in the *J. of The A. M. A.*, December 1, 1917, p. 1905, one reads: "One of the great causes of feeble-mindedness is heredity, and the birth rate among the mental defectives is found to be approximately twice that of the normal population." The majority of cases of feeble-mindedness are congenital, or natively and postnatally occasioned—not hereditary—and according to Weismannism and the facts in general such feeble-minded *do not* reproduce their kind.

33. I have noted these facts (with full reference to the literature) in a study on "Heredity," *MEDICAL RECORD*, February 24, 1917, and on "The Degenerate: Born Delinquency and Criminologic Heredity," *Archives of Diagnosis*, New York, April, 1917.

34. In his criticism of Spearman's contention that by gauging certain tests—i. e. number-adding ability, pitch discrimination, rapidity of writing and text-completion, etc.—one finds a high correlation among them and can use this as an index to the general ability or intelligence. *l. c.* Vol. II, p. 721. See also Stern, *l. c.*, p. 65. Stern, by the way, also doubts Spearman's findings; *l. c.*, p. 78. See also Meumann's paper, No. 15a, p. 20.

35. Seashore, C. E.: "The Binet Tests," *J. of Ed. Psycho.*, 1912, III. Ziehen also called attention to the "partial intelligence defect" which he states has not been sufficiently considered, "Beitrag zur Beurteilung des sogenannten, Moral Insanity," etc. *Der Praktische Arzt.*, Nos. 19-20, Leipzig, 1915; see also p. 190 of the article mentioned under 37.

36. See Anton's "Uher Krankhafte moralische Arbartung im Kindesalter," etc., *Jurist und Psych. Gränzfragen Halle*, 1910, p. 5, etc.; Th. Ziehen, "Die Geisteskrankheiten des Kindesalters," Berlin, 1915, pp. 69-70.

37. See, for instance, the very instructive study of "Congenital Aphasia and Feeble-mindedness: A Clinical Diagnosis," by Lightner Witmer, *The Psychol. Clinic*, Vol. X, No. 7, December 15, 1916.

38. I find the following interesting and pertinent paragraph by S. T. Orton in the annual report (1917) of the Pennsylvania Hospital, p. 23: "In many cases of chronic course the mental deterioration is apparently not of the same degree in all of the mental fields. Thus one case may be able to express spontaneous thoughts better in writing than by speech; in another repetitive speech will be well retained, while propositional or spontaneous speech is much disturbed. A thorough study of these variations might serve to indicate the best methods for an attempt at reeducation, or might serve as a guide for the best form of occupation therapy, and would at the same time be of considerable scientific interest."

39. v. Monakow, C.: "Über Lokalisation der Hirnfunktionen," Wiesbaden, Bergman, 1910, p. 19. Discussing psychic shock, he writes: "It is interesting that already here one finds present an election of very special central 'somatic innervationpaths' (as the optic center) whose function here misgives."

40. Since writing the above I have come upon a notice

of B. Parker's "The Psychograph of Rossolimo," *Am. J. of Insanity*, 1916, 23, which deals with these tests.

44. As, for instance, the *defining* test. See O. Bober-tag, "Über Intelligenzprüfungen," etc., Barth, Leipzig, 1914, pp. 50-58. See also *The Psychological Review*, Vol. XXIII, No. 6, p. 489, etc.

60 WEST EIGHTY-FIFTH STREET.

MASTOIDITIS.*

By WM. H. HUNTINGTON, M.D.

WASHINGTON, D. C.

JUNIOR SURGEON, EPISCOPAL EYE, EAR, NOSE, AND THROAT HOSPITAL, D. C.; CAPTAIN, MEDICAL RESERVE CORPS, U. S. ARMY; CHIEF, EYE, EAR, NOSE, AND THROAT DEPARTMENT, WALTER REED GENERAL HOSPITAL, WASHINGTON, D. C.; CLINICAL INSTRUCTOR IN LARYNGOLOGY AND OTOTOLOGY, GEORGE WASHINGTON UNIVERSITY MEDICAL SCHOOL; INSTRUCTOR IN OPHTHALMOLOGY, ARMY MEDICAL SCHOOL, WASHINGTON, D. C.

HISTORICAL.—As early as 1656 we find Johann Riolan and Rolfinck advocating mastoidectomy for the relief of deafness and tinnitus. Their ideas were logical, in a degree, as they hoped to equalize the atmospheric pressure on both sides of the tympanic membrane.

Petit (1674-1760), the French surgeon, was probably the first to open the mastoid for a suppurative condition, but it was a Prussian (Jasser, 1776) who was credited with the first operation, although his work was done subsequent to Petit's. The operation came into disrepute largely through the death of Baron Berger, who was physician to the King of Denmark. He submitted to the operation for the relief of tinnitus and deafness. His death was no doubt due to meningitis as a result of poor technique.

Schwartz, in 1873, finally succeeded in establishing the mastoid operation upon a firm otological basis by applying anatomical knowledge to the procedure. His success was attained after such men as Pagenstecher, Follin, and others had attempted to revive the operation without success. The operation remains to-day, even with its many modifications, practically as Schwartz introduced it.

The operation again fell into disfavor, probably owing to poor results and deaths which were in turn the results of bad technique, not to be resurrected again until the latter half of the nineteenth century.

Anatomical.—The mastoid process varies in shape and form in different persons, being larger in the muscular than in the non-muscular. It is in this process that the mastoid cells are found lying between the cortex and the inner table. The cortex varies in thickness from .5 mm. to 10.00 mm.

The mastoid process is occupied by pneumatic cells which vary in number and size and which communicate with the mastoid antrum; this in turn communicates with the tympanum (Cunningham¹) through the aditus ad antrum (Ballenger²). Embryologically the mastoid antrum is part of the middle ear, while the cells are not. The antrum and cells are lined with ciliated epithelium. We

occasionally find very large cells behind the sigmoid sinus and sometimes extending into the pyramid of the temporal bone, encroaching on the semi-circular canals.

The antrum is found at birth practically fully developed in size and placed rather superficially. The inner table forms part of the wall of the middle fossa and presents at operation the convexity of the sigmoid fossa. Korner³ finds that the fossa on the right side is usually further forward than the left. There are many variations in the position and size of the sinus wall, varying from the superficial anterior position, often found in children, to the deeply placed posterior sinus occasionally found in adults. According to Schultze,⁴ the cranial fossa lies higher on the right than on the left side.

Etiology.—The common and usual causes of bacterial invasion of the mastoid with the accompanying subjective and clinical symptoms, which may or may not be pronounced in their severity, are some of the exanthemata of childhood and the various types of "head colds."

Adenoid hypertrophy is a large factor in the etiology, particularly if the mass is situated in and around the lateral folds and the eustachian orifice. There are several facts that make me think that adenoid hypertrophy is one of the greatest etiological factors in middle-ear trouble and subsequent mastoid invasion. We rarely see middle-ear infections in children who are not subject to repeated "head colds," unless the infection is a sequel to one of the acute infectious diseases, and in these same children an examination of the epipharynx will usually reveal a mass of adenoid tissue.

Mastoiditis as a primary condition or idiopathic, as it is called by some writers, is indeed a rare condition, yet it undoubtedly does occur at times, and the hypothesis offered is quite as logical as that offered to explain primary infection in other remote organs, as for instance the lodgment of the tubercle bacillus in the epiphysis of the femur in hip disease, and in the vertebræ in Pott's. Many cases of this condition are to be found in the literature, but the diagnosis in many instances has been questioned by competent otologists. Dabney⁵ of this city recently reported two undoubtedly authentic cases of primary mastoiditis, as has also Broder⁶ of New York; one of the latter's cases was traumatic. Compound fractures of the skull are rarely a factor in this disease, yet there are cases reported. A chronic suppurative otitis naturally is always a menace and liable at any time to cause an acute mastoiditis or some of its more grave complications, such as sinus thrombosis, brain abscess, or meningitis.

Symptomatology.—As a rule there is a sequence of events something like the following: An acute coryza, sudden pain in the ear, which becomes intense, spontaneous rupture of the membrane, followed by relief from the pain. Subsequently the discharge may become less and post-auricular pain manifests itself, sometimes with edema.

The subjective symptoms may be very vague indeed and will vary in intensity according to the temperament of the individual and certain bacteriological and pathological factors.

The objective symptoms, together with laboratory findings, may be classical, but they are more apt not to be. I do not know of any other one sur-

gical condition that can be so perverse and unreasonable.

One naturally expects to have a leucocytosis, but there may not be any. One naturally expects a pyrexia at some time during the preoperative period, yet one often sees cases with normal temperature and pulse.

It is futile to attempt to formulate any classical picture or group of symptoms, either objective or subjective, for our guidance as to operation in these cases, for many times we shall find our gravest cases without the textbook signs, and if we await their appearance we very likely will have the opportunity of watching the advent of a meningitis or sinus thrombosis.

Gorham Bacon⁶ reports the laboratory findings of Dixon on 5,496 cases in which smears had been made from the discharging ears. In 26.6 per cent. there was mixed infection; the majority of these were chronic; in 24.8 per cent. streptococcus was the predominating organism; in 12.2 per cent. pneumococcus; in 7.4 per cent. staphylococcus; in 4.8 per cent. *Streptococcus mucosus capsulatus*, and in 1.8 per cent. Vincent's spirillum. The remaining 22.4 per cent. were miscellaneous, negative, etc. Among them were placed the *B. pyocyaneus*, *B. diphtheria*, *B. tuberculosis*, *B. coli communis*, Friedlander's bacillus, etc.

Dixon finds that the pus in the external canal usually shows mixed infection, but the causative organism is found in the mastoid pus, sinus, or brain when these organs are involved. Bacon pays great respect to the *Streptococcus mucosus capsulatus*, and says he finds extensive bone necrosis when this organism is the invader.

Diagnosis and Aids to Same.—As a rule the general practitioner is the first consulted about the pain in the ear or the discharge. This is the time to devote serious attention and treatment to these cases, for the earlier we can see them and start treatment the more we can do toward the conservation of not only hearing but life.

The chief symptoms I rely upon to guide me as to operation are: The continuance of postauricular pain with or without edema, together with pulsating discharge from the ear, and possibly sagging of posterior and superior meatal wall. The presence or absence of pyrexia and a leucocytosis do not influence me if there is mastoid pain which continues with or without a discharging ear.

We must also be on our guard for the unusual, and differentiate a local from a reflex pain. Necrotic lesions in the molars, unerupted molars, and tonsillar and tubal inflammations will all give us at times typical mastoid pain. External otitis sometimes simulates mastoiditis, and the two may co-exist.

Rarefying osteitis of the mastoid bone is a rare condition, which will give continual local pain. The diagnosis of this condition is usually made under the microscope. C. W. Richardson¹² reports a case of this sort in the Transactions of the American Otological Society, 1911.

Material aid and information may be acquired from the roentgenologist, which will greatly assist in making one's diagnosis.

On the other hand, we often see cases which have neglected to seek advice or treatment, in which no

paracentesis has been done or, just as bad, only a pin point puncture made; or possibly a spontaneous rupture has occurred with only a small opening. This class of cases is seen early, even though they present a bulging of the membrane, if a thorough incision is made and they be watched carefully, will often go on to complete recovery.

In children we are much more apt to note the evidence of sepsis in the marked rise of temperature, and Kopetsky¹ says that convulsions are often observed when the membrane tympani remains imperforate.

Pulsation of the pus is considered as a valuable sign by some and as an indication for operation, but this must be considered along with the other evidence.

The roentgenologist may be of great aid to us, and it is surprising his assistance is not oftener sought. A comparative plate, showing both mastoids, taken by a competent man, is in inestimable value in obscure cases. Dixon, of the New York Eye and Ear Infirmary, and Law, of New York, have done a great deal of work along this line and have made themselves most proficient in their interpretation of plates. The sigmoid sinus may be outlined and in cases of necrosis of its wall the extent of the same may be observed prior to operation. Also remote cells in zygomatic root or in occipital bone may be shown and reached when operating. I wish to state here that it is quite essential that every pus-bearing cell be reached and opened if we desire a satisfactory termination, otherwise we will probably have the embarrassing misfortune of doing a secondary operation.

In a paper read by Dixon¹ before the Medical Association of Greater New York he says: "It is not to be understood that the blood count, the form of infection, or positive x-ray findings, alone can be relied upon to any considerable extent as determining the necessity for a mastoid operation. The clinical symptoms are all important; without them our modern aids are of little value. We may have a rather virulent streptococcus infection in the canal, or a pneumococcus infection which looks vicious in the smear, but both may recover after a myringotomy, though there may be considerable mastoid tenderness. In either streptococcus or pneumococcus cases (though we believe that more liberty can be taken with the latter as a rule), the danger signal may be a sudden rise in the polynuclear count, with or without an increased leucocytosis, especially the latter. A positive x-ray plate will again settle the diagnosis, though the clinical symptoms may not alone be sufficient to indicate the mastoid operation."

John J. Kyle⁸ in a recent article lays particular stress on the pulsation of the discharge from the middle ear as a guide to early operation. But even this valuable sign is often absent, and, indeed, in some cases that are most urgent and require immediate operative intervention, we may have no discharge to pulsate. Neither is it necessary that pus should fall in a spectacular cataract upon opening the cortical cells or the antrum to justify the procedure.

Cases of bilateral otitis media with possible mastoid involvement are indeed trying cases from the standpoint of both the surgeon and the patient and

they call for infinite care and patience, particularly if one is unfortunate enough to have some such complication as a sigmoid sinus thrombosis. One's judgment is taxed to the utmost in such a case. Here again is where the roentgenologist can lend us very material aid, particularly so if he can show us on which side the thrombosis is located.

The so-called latent mastoiditis is a condition one has to deal with occasionally. These cases are those in which the surgeon has temporized too long, or the patient has not sought advice until finally the acute symptoms have subsided, the patient has established a certain immunity to the toxemia, and to all apparent purposes the mastoid has cleared. We find a persistent suppurative otitis media which may vary in quantity and may be intermittent. The pyorrhea resisting all measures, operation will usually reveal a completely disintegrated mastoid process. These cases are particularly vicious, as they usually leave a certain amount of permanent impairment of hearing. Mithoefer,⁹ Hays,¹⁰ and others have reported many such cases in the literature.

Otitis externa or furunculosis of the external canal is not always the simple little "pimple" one often hears it spoken of. There very often is an acute suppurative otitis media concealed behind the edematous and painful canal, and the furuncle is merely the result of a secondary infection in the skin due to the discharge of pus.

Chronic discharging ears in children call for a deal of thoughtful treatment. Some cases will yield beautifully to local measures, possibly with vaccines. These are usually the cases with large central perforations and a chronic discharging middle ear and mastoid. One may have to resort to a simple mastoidectomy in these cases. Hypertrophied adenoid tissue and diseased tonsils should be removed if present, but the parents should be warned not to expect wonders following the procedure, as their removal will certainly not put an end to an otorrhea with accompanying necrosed bone.

Another class of cases will present a chronic discharging ear with adhesions in the tympanum, polyps, and detritus, with marginal perforations, or no membrane at all. Sometimes these cases will clear up nicely under local measures which provide good drainage and the cavity will dermatize and remain dry, nature having done a neat radical operation. More than likely, however, a radical operation will be necessary to clear up the discharge entirely. In children this should be kept as a last measure and be resorted to only after every other means has failed.

Too often indeed do we see children allowed to grow up with discharging ears, in the vain hope that at some time during their adolescence they will drop this burden; this is a delusion too often fostered by the medical profession, surprising as it may seem. Aside from the possibilities of intracranial complications, the autointoxication usually stamps itself upon the child in some unmistakable manner. Aural furuncles, impetigo, and eczema are among the list of ailments the pus gives rise to.

Our attention cannot be too strongly called to the care of the infants' and children's ears. From

a purely sociological standpoint we owe it to the community not to allow any more cases of acquired deaf-mutism. If a child loses its hearing before it learns to speak it will in all probability become a mute. John Dutton Wright¹¹ states there are approximately 50,000 deaf mutes in the United States.

It should indeed be a stimulus to better care of the children's ears when we reflect upon the tragedy of these lives, and the ostracism they not only have forced upon them, but inflict upon themselves rather than be subjected to the ridicule that is only too readily forthcoming from the average heartless youngster.

J. J. Kyle⁸ thinks, and rightly too, that a lumbar puncture and cell count should be made in all cases in which there is a suspicion of intracranial trouble, preceding an operation.

Cases of mastoiditis seen early should yield nearly 100 per cent. of cures, while temporizing too long and neglect yield a large mortality. Delay is less likely to prove serious in the young adult than in the infant and the aged. In the latter there is usually some otosclerotic change and the pus if not draining well is apt to seek outlet into the cranial cavity.

Kopetzky¹ thinks that in the usual uncomplicated cases it is wise to delay operation until after the first "hyperemic stage," as he calls it, has passed. His theory is that after the first 24 or 36 hours the blood in the smaller venous channels has become thrombosed, and that the chance of bacterial invasion of the sinuses is much lessened. Also the body resistance is better.

Some of the grave complications that may ensue are sinus thrombosis with possible metastases, brain or epidural abscess, and meningitis, either serous or purulent. The former type may recover; the latter rarely.

I would again urge early operation when mastoid symptoms continue rather than temporize and experience that hopeless feeling which one has when he sees the unmistakable signs of meningitis.

Comparative x-ray studies will be found to be of inestimable aid, particularly in the chronic suppurative cases and in the acute cases with unusual features.

Much may be accomplished by free and early paracentesis in suppuration of the middle ear and in many cases of acute catarrhal otitis, as this will often lead to spontaneous recovery.

I believe in the use of vaccines and local measures, though there is much for us to learn about vaccine-therapy.

Some Contraindications to Mastoidectomy.—Hemophilia, though rare, undoubtedly does exist, and should one encounter a hemophiliac who develops mastoiditis, he would, I think, be justified in delaying operation until all abortive measures have been tried.

Advanced tuberculosis and diabetes in a patient who is suffering with mastoiditis are considered contraindications to operation unless local anesthesia is resorted to. Even fairly well advanced tuberculosis may not prove a contraindication, as the operation can be done under local anesthesia or nitrous oxide and oxygen in certain cases.

Indications for Operation.—Summarizing the conditions which would indicate the simple mastoid operation, we find:

1. Cases of acute mastoiditis, with persistent pain on pressure over the tip, or antrum. Persistence of fever after a successful paracentesis has been done, or in which we find a sagging of the posterior superior meatal wall.

2. Cases of acute suppuration of the middle ear, with dizziness, vomiting, nausea, or beginning facial paralysis, or with signs of intracranial or labyrinthian involvement.

3. Cases of long standing middle-ear suppuration which resist all local measures, and because of good hearing and other reasons do not indicate a radical mastoid.

4. Cases of persistent mastoid pain either with or without other symptoms, which cannot be accounted for in other ways.

5. Cases of subperiosteal abscess.

In closing I would quote Whiting," who says: "As a life-saving measure few surgical procedures equal, and none surpass, in efficiency the modern mastoid operation."

TIMELY REMARKS ABOUT THE TREATMENT OF MALARIA.

By BEVERLEY ROBINSON, M.D.

NEW YORK.

IN view of the large number of cases of malaria at the present time, in our cantonments and in the allied armies abroad, I wish to direct special attention now to two remedies, which I consider to be of the highest value, when quinine fails to cure the patients.

The treatment of malaria with quinine is time honored and general. No other remedy takes its place efficiently, it is now stated by our highest authorities. Methylen blue, salvarsan, and a few other remedies are spoken of when the case is protracted, or recurs; or when, as happens in some instances, quinine is badly borne and produces un-

pleasant and sometimes even seriously disquieting symptoms.

In pernicious forms of fever, intravenous or intramuscular injections of quinine are utilized, but they are not without drawbacks. They are painful and, unless given with great care, and a solution is made of certain salts, they are apt to cause swelling or even abscess at the site of injection.

In former years, Warburg's tincture or Warburg's extract was frequently given in obstinate or threatening cases of malaria, with the happiest results. Now it is scarcely ever used and, indeed, the textbooks either mention it only casually or do not refer to it at all. This, to me, is lamentable. In certain forms of malaria, and especially those contracted in South America, on the Isthmus, or in the Far East, nothing remedial equals or approaches the value of Warburg's tincture or extract. The latter should be given in five grain capsules, three to six times in the twenty-four hours, with or without aloes, depending upon the effect on the bowels. If they become too loose, the second should be given.

Sometimes, when we prefer not to give Warburg's extract, we can recur very advantageously to the use of Huxham's tincture of bark. To be effective this should be given in frequently repeated teaspoonful doses, as often as every two or three hours, in a little sherry wine or in water.

In the last edition of Dieulafoy's "Practice of Medicine," the author speaks of the great value of cinchona bark, when quinine fails utterly to cure the patient. Dieulafoy prescribes the powder of cinchona, but to me the tincture is preferable, as a less objectionable dose.

I cannot speak too strongly in behalf of Warburg's extract and the compound tincture of bark in the treatment of chronic, recurring, or even pernicious malaria. In looking back over my practice of a few decades, I can recall not a few instances where quinine failed me and where, fortunately, Warburg or cinchona helped cure the patient in a remarkable and very satisfactory manner.

I do not agree with Osler, therefore, when he states that one who can not cure malaria with quinine should abandon the practice of medicine. Rather, I am in accord with Prof. MacLean, Loomis's Practical Medicine, 8th Ed., p. 887, who says that "he has seen the most hopeless cases—those manifesting a degree of severity which seemed to preclude the possibility of recovery—commence to convalesce as soon as the patient was brought under the influence of this remedy," *i. e.* Warburg's tincture.

Anyone who reads the treatise of Huxham, written over one hundred years ago, and uses the formula for bark which he there so strongly emphasizes, will have his convictions strengthened by what he reads, as mine have been.

I was stimulated to write this brief article by reading the editorials in the March and April, 1918, issues of the *Therapeutic Gazette*, by Dr. H. A. Hare of Philadelphia. In these editorials Dr. Hare dwells particularly upon a valuable paper, published by Captain David Thomson in June and July, 1917, issues of *Journal of the Royal Army Medical Corps*, entitled "The Diagnosis and Treatment of Malarial Fever."

OPPORTUNITIES FOR PREVENTIVE MEDICAL WORK IN THE DISPENSARY CLINIC.

By ANNA MANN RICHARDSON, M.D.,

NEW YORK.

THE work in a hospital is limited by the number of its beds, but the cases coming to a dispensary are limited only by the standing room in the building, and even on the street. During one year 3500 new patients came to the General Medical Clinic at Cornell University Dispensary for treatment. There have been approximately 11,000 revisits, making a total attendance at the clinic of 14,500 patients for the year, or between 50 and 100 patients a day in this one department. The clinic lasts two hours. Four to seven doctors are in attendance, who give undivided attention to the patients during the clinic hours, but who are not free to devote further time to the work. Thus patients who need medical care only and general hygiene directions can receive adequate treatment in the clinic; but the cases of more chronic condition, where the patient needs instruction in methods of living and readjustment of his work in addition to medical care, require a different plan of organization from our present dispensary system.

The first step in bringing about a reorganization is to realize the opportunity. During 1916 I interviewed 500 patients coming to the Cornell University General Medical Clinic. They were selected at random, with the only requirement that they be wage-earners, as we were anxious to obtain information regarding the hazards of industry. This was done as part of an inquiry into the effects of sickness among wage-earners carried on by the Russell Sage Foundation.

Of these 500 patients, 8 per cent. were suffering from mild conditions of short duration, such as colds, acute indigestion or tonsillitis, from which they would probably recover in two weeks or less, with medical care. About 26 per cent. were more seriously afflicted, having conditions like acute bronchitis, pleurisy, whooping-cough, influenza, etc., for which the prognosis for recovery with care and treatment would be two months or less. Four per cent. of the patients required operations, as appendicitis, gallstones, varicose veins, hernia, and gastric ulcers.*

The remaining 61 per cent., or 303 patients, needed careful regulation of their lives and adaptation to their environment to gain in health. A small number of these, 19 in all, were suffering from diseases that would grow steadily worse, as inoperable cancer, advanced Bright's disease, renal tuberculosis, Paget's disease, etc. One hundred and twenty-three patients had conditions from which they might absolutely recover, as gastritis and many forms of indigestion, enteroptosis, neurasthenia, and some of the rheumatic conditions. The remaining 161 patients were suffering from diseases which would always cripple them more or less, and for which they needed to modify their lives. They could be comfortable and reasonably efficient, but they would never be free from some slight handicap. I have classed tuberculous and thyroid cases,

nephritis, and valvular cardiac lesions all in this group.

We see from this that about two out of every five patients coming to the clinic could have their needs met in the clinic, or possibly by hospital care, as in the surgical cases; while the other three patients needed a readjustment to their environment, either to regain their health fully, or to live comfortably with a permanent physical handicap.

Beside medical care, two elements are essential in treating the more chronic cases: First, the re-education of the patient; and second, the removal of strains from without. The following case illustrates the possibility of meeting both these needs:

Mr. H., a night watchman in a downtown office building, came to the clinic, complaining of dizziness, pain in the legs, nervous apprehension, occasional headaches, and loss of weight. He was a well developed man, fifty-eight years old. His physical examination showed a systolic blood pressure of 200, a slightly hypertrophied heart, and a mild nephritis. He worked twelve hours seven nights a week, with one night off a month. Every hour he was obliged to punch a time-clock and occasionally had to tend the furnace.

The employer of this man appreciated his services and wanted him to regain his health and maintain his ability to work. He therefore gave him a week's vacation, and planned to readjust the work so that he might have one night off every week.

A visit to the home showed that the man acted as janitor and had first floor rooms, with poor air and constant noise from the halls and street. His wife agreed to move to more quiet and sunny rooms. The man himself did not like to eat alone at night, so neglected to do so. After explaining to him the need and advantage of taking nourishment during the night, and suggesting things to eat at that time, he became interested to carry out the directions.

In this case, aside from the medical care, which was followed carefully, the employer relieved the industrial strain, the wife became interested to adjust the home situation, and the man did his share by eating at night. These three elements were all essential to his cure.

Night Work.—The above case is not unusual. Seven other night watchmen were interviewed. All worked seven nights a week; all had various duties, as dusting, cleaning, punching timeclocks or fire signals; all but one worked eleven to fourteen hours a night. This one exception was an employee in the City Dock Department, who worked on a lighter eight hours each night and received \$17.50, the highest pay for any man in the group. One of these men needed an operation, but the other seven had developed chronic conditions for which they needed re-education.

We found 64 men working at night. Some were on shift, working nights every other week; some as waiters and elevator men worked until 1 a. m. every night; marine firemen and sailors worked four hours in the night and four hours in the day time; some men were employed on trolley cars or sold tickets in elevated railroad stations. The difficulty in all these cases is with the industrial situation. Forty of these 64 men worked seven days in the week. Of these 40, 12 worked 56 hours, while the remaining 28 worked anywhere from 60 to 112 hours. The hours are beyond the men's control, and while in all cases they are not directly harmful, we know that the continual fatigue of long hours predisposes to degenerative changes. The exact difference in strain between day work and night work

*Seven cases, or 1.4 per cent, had not been sufficiently diagnosed to form a prognosis.

has not been demonstrated, but we find that instead of a ratio of two curable to three needing re-education among all those interviewed, the ratio among night workers is two to five.

The ages are not unlike those of the general group. Among night workers 46 per cent. were under thirty-six years of age, while in the general group 47.8 per cent. were under thirty-six.

We can eliminate age as a factor and return to the fact that the number of seriously crippled men among night workers is nearly twice as great as among sick people in general. The figures are few and suggestive, rather than conclusive, but the point is that night work in itself is a special hazard, that at the present time it is not so recognized, for night workers are given longer hours than day workers, even on the same job. Night work is a hazard imposed on workers by the industrial system and one which they can in no way control.

One more case of night work, the one with the longest hour schedule—112 hours a week—shows how the individual is a helpless tool in the hands of the industrial system.

Mr. M. is employed on a railroad in New Jersey, running as freight brakeman from Elizabeth to Camden. He works from 11 P. M. until 3 P. M. the following day, seven days a week. The run takes these hours. He has to have a home at each end of the line. His family lives in New York and he visits them the three or four times a week he is in Elizabeth. He spends about six hours with them, all the time he should be sleeping. The duties of the freight brakeman are to help load and unload cars at stations, and between stations to ride on the outside of the cars. Sleep is impossible from the constant danger of falling off. Meals are carried in a dinner pail and eaten at odd moments and in all weather.

Will it be possible ever to keep this man well doing that work?

To improve permanently the health of men working at night we shall have to demonstrate this special hazard, and interest employers so to adjust their work that this strain shall be lightened by shorter hours and by one day off each week.

Alcoholism.—Another hazard for which public opinion is largely responsible is the temptation to take stimulants. This comes to men in various forms. The cause given most among the men coming to the clinic is that it helps them to sleep when fatigued beyond their endurance. This fatigue may be from work, but is also frequently from lack of interest in life and opportunity for recreation.

The case of Hans J. is of this latter type. He is a Norwegian, an expert on skis, and has also won silver cups for running in his native land. He is blond and splendidly built, but came to the clinic intoxicated. A few days later he came again to the clinic and told of his struggles with alcohol. He came to America eight years ago and soon established himself in his trade of house painting. He married and settled down in a small apartment in the Bronx. His wife, a very excellent housekeeper, found all the field she needed for self-expression in her small apartment and her little daughter. She never cared to go out with her husband or to entertain his friends. They disturbed the exquisite order of her home. Mr. J., used to activity in the open air, with friends and social life, found himself restless and unable to sleep. He started with beer, increasing the amount gradually, but finally found that whiskey would more effectively control his restlessness. This continued six or seven years, when his wife and daughter returned to her people, leaving him to live alone in furnished rooms.

In this case the restlessness for which he sought

relief in drink was the normal revolt of his muscles at their enforced idleness. Surely he could have found friends and companions with whom to exercise, but he was a stranger in a strange land and did not happen to meet with anyone who could direct him in right lines. He was suffering from tuberculosis and was sent to Sea View Hospital.

In the group of 383 men reporting on alcoholic indulgence, we found 249, or 65 per cent., had been addicted to the use of alcohol in some form. In the Cornell Clinic the doctors inquire the exact number of glasses of beer or whiskey consumed a day, so that our figures are not based upon the judgment of the patient. Ninety-four of the men claimed to take an occasional glass of beer, but only for social purposes with their friends; 77 were in the habit of having beer daily and occasionally whiskey. The remaining 58 took both beer and whiskey to excess, so that they were markedly affected by its use. Four of this group were periodic drinkers. They absolutely abstained from alcohol in any form for a week or two at a time, and sometimes even for months, but when they did drink they would completely lose themselves for days or even weeks. We found this habit of periodic drinking to excess among men working continuous hours without sleep. The case of a marine painter will illustrate this point:

Mr. T. paints the bottoms of boats when on dry dock. Since it is important for these boats to return to the water as soon as possible, while they are in dock the painters work unceasingly. The work is casual, so that when it is to be had the painters like to work steadily every minute. The method of pay also stimulates the desire for overtime. The usual rate of 50 cents an hour is paid between the hours of 6 A. M. and 5 P. M.; for all other hours 75 cents is paid, and on holidays and Sundays the men receive \$1 an hour. This man has found as a matter of practical experience that after 20 hours of steady work he cannot sleep. Experience has also taught him that beer helps him to sleep. After he had worked 20 hours for three or four consecutive days beer would lose its effect, but whiskey would bring the dulling of the senses he longed for. After several years he lost his ability to stop drinking and would usually be dead to the world for from three to six weeks after a long stretch of work. After one of these periods he would have a horror and distaste for whiskey which would last until he again became "over" fatigued. The temptation to start drinking after a period of work is increased by the fact that the men are paid by checks and, in the ever present saloons, they can get these checks cashed if they buy something.

Marine firemen are a group of workers much addicted to alcohol. One man told me he was given four ounces of gin every time he went on duty, claiming that this was essential in order to tolerate the heat and fatigue of the work. Boiler repairers and longshoremen have the same type of temptation as the marine painter, the long continuous hours followed by inability to sleep.

Waiters, bartenders, and saloon porters are tempted by the constant presence of drink. Six out of the 58 men drinking to excess were employed in this way. The most hopeless fight was being put up by a young man employed as a rectifier of spirits. His duties require that he taste the whiskey as he sweetens and colors it. This man tried many ways to master the temptation. Finally he got a job as waiter at Brighton Beach for the summer and went for six months without stimulants. On his return to the city, his old employer urged him to come back to the work, and, believing himself cured, he re-

turned, to find in two months that the desire was again his master.

The occupations of the 58 men addicted to the use of alcohol in excess, although varied, have certain common characteristics. The list follows:

Drivers and shippers	9
Longshoremen, marine firemen and painter.....	7
Boiler makers	2
Workers in saloons and handling liquors.....	6
Masons and roofers	6
Stationary firemen and engineers.....	6
Painters	5
Caring for horses	4
Machinists	4
Plumbers	2
Miscellaneous*	7
Total	58

*One each of the following: cook, elevator man, butcher, caretaker, oyster opener, milk-man, and carpenter.

The men frequently blamed their work as the cause of their intemperance. The firemen drank to keep cool, the butcher, working in an ice house, drank to keep warm, the masons drank to overcome the dryness in their throats, and the oyster opener, to overcome the effects of the water in which he was obliged to work.

None of these men had sedantary occupations. The absence of garment workers, who composed 7 per cent. of the entire group, suggests another element. Practically all the garment workers were Hebrews. Looking at the nationality of the excessive alcoholic group, we find only one Hebrew, who was the owner of a saloon and felt his drinking a business necessity. The predominant nationality among the heavy drinkers was Irish. Fifty per cent. of these 58 men were Irish, while in the entire group of 412 men only 23 per cent. were Irish. Hebrews composed 22 per cent. of the entire group, but among the excessive users of alcohol were less than 2 per cent.

Whether the cause of the alcoholic indulgence is the strain of the work, the early training of the individual, or his heredity, does not relieve the clinic of the responsibility of assisting individuals in overcoming its temptations and of educating the community in sane and scientific methods of meeting this problem.

Exercise and Recreation.—One of the most vital ways to help solve the problem is to develop opportunities for wholesome recreation and exercise. The responsibility of industries in which overfatigue is an essential to obtain a living wage must not be minimized, but the lack of exercise and recreation among these 500 men and women is one of the major strains of their lives. Of 440 patients who reported on this subject, only 14 took any form of systematic exercise outside of their work. Fifty-six other patients walked sometimes solely for air and exercise, but with no regularity or aim.

The type of exercise that the 14 patients were following was somewhat varied. Three danced, four were learning prize fighting, one was a member of the National Guard, who drilled each week and spent two weeks in camp every summer, three attended gymnasium regularly, two did special exercises prescribed by the clinic, and one, a paranoiac, had developed a system of auto-cheiropneumatic ad-

justments performed suspended from his doorway, believing that he could straighten a kyphosis he had had all his life.

The answers regarding recreation were, for the most part, free from all semblance of real recreation. We asked, "What do you do to enjoy yourself when not working?" Most of the patients replied: "Enjoy my family," "Help my wife around," "Read newspapers or novels." A small number attended evening school, and a still smaller number went often to the movies, while three attended dances.

This lack of exercise and recreation has several causes. One hundred and thirty of the patients are doing heavy work, and are fatigued beyond the possibility of enjoyment in their free time. None of these people were in normal health. Probably in a group of the same size in the general community we should find a far greater variety in the forms of exercise and recreation and a larger proportion of individuals participating in them. In our dispensary group we found many men who had begun work when only nine or ten years old. They had had no experience in recreation as we understand it, and there was no exercise they could do with sufficient skill to find recreation in performing it.

I was deeply impressed by this result of early work in the many victims of the foreign apprenticeship system that are included in our group. This system develops wonderful skill in its workers, but at the cost of the ability to relax and enjoy life, when work is begun before the age of fourteen. One man told of taking out bastings at the age of three. He cannot remember when he did not know how to sew, and was daily required to do this. One surprisingly serious Irish cook started in at the age of nine to assist his father, who owned a slaughter house. He reports: "I did the lighter work, like killing the sheep." Fortunately, in this city the employment of such young children is almost a thing of the past, but we still lack resources for wholesome recreation.

Diet Instruction.—To return for a moment to alcoholism, one essential element in its relief is diet regulation. In this essential a clinic has special opportunities to educate not only its alcoholics but all its patients. To prescribe a diet requires a more intimate knowledge of the patient's habits of life and his physical condition than is needed to prescribe a drug. This is especially true in this city, where in our small group we found patients of 25 nationalities and four races. Two incidents which occurred at the Cornell General Medical Clinic, where special attention has been paid to preparing diet lists for the more common conditions, show the need of more individual attention than the crowded clinic hours permit.

A man suffering from psoriasis had been given a diet list in the Skin Clinic. After two months' care he was losing weight, and doing so poorly, although the skin condition was improving, that he was referred to the General Medical Clinic. Aside from the skin condition his physical examination was negative except for the marked undernutrition. He showed his diet list, and said he had not violated its rules. Further conversation showed that bread and milk were the only articles on the list with

which he was familiar, and that were within his reach financially. In response to a question about the quantity of milk the doctor had said about a quart a day. So this faithful soul had been living for two months on a quart of milk and a five-cent loaf of white bread a day.

The second instance occurred in the Thyroid Clinic. A poorly nourished patient was told to eat plenty of food, and bring a list of just what she ate to the doctor next day. The list follows: Breakfast, ham and eggs; dinner, two eggs, supper, six chops. The majority of the clinic patients would not have been able to afford this menu. Both these cases illustrate the need of knowing the patient's habits and financial resources if a successful diet is to be prescribed.

Industrial Cases.—This year a special effort was made at the Cornell Clinic to care for industrial cases. Men who had obviously been injured by their work, as painters with lead poisoning, and stone cutters with phthisis, were given special attention. An essential element in the care of these cases is change of employment. Here a dispensary is dependent on making employers and employment agencies recognize that if a man is crippled in one direction he may still be a most useful worker in other lines.

The chief hardship in this change of occupation comes on the patient who must usually face a reduction of wages, for the change is almost always from a skilled to an unskilled trade. The case of a young Jewish boy earning \$8.00 a week shipping wrapping paper shows this. He had a mitral regurgitation, so that it was necessary to change his job. An opportunity to learn to be a switchboard operator and earn \$5.00 a week he scorned because of the small pay, and remained idle for several months. Painters, also, who are in the habit of earning \$4.00 a day, must be driven to the most dire necessity before they will consent to accept a job delivering for a grocer for \$10 or \$12 a week.

One exception to this experience is noteworthy. Mr. S. was a foreman in a room where woolen braids were woven. He earned \$30 a week, had a good home, with a wife and one child. He developed asthma and suffered intensely from it for two years. At the Cornell Clinic he was told he must do outside work. He gave up his job and went to peddling bananas from a push cart. If he had a fortunate week he could earn about \$8. Even cheaper rooms could not make up his weekly deficit. After his savings were exhausted his wife went to work at her former trade of making shirtwaists, leaving their little child at a nursery each day.

When such a lowering of the standards of living is necessitated through a change of work, we sympathize with the men who prefer to risk lead poisoning rather than to subject their families to such hardships. It is taking an unknown risk in preference to accepting a known hardship. One Indian who refused to accept inferior wages had been out of work a full year, his father sending him money regularly. This man was an expert horseman, and had performed in Buffalo Bill's show from earliest infancy. Four years ago he served two years at the Hippodrome; for a year after this he did movie acts. In these war times Indian movies are unpopular, and he has had no work. In his usual line he earned \$50 to \$100 a week, and resented as an insult the suggestion of smaller pay.

These are a few of the many complications surrounding the problem of change of work. It is a problem which dispensaries should assist in solving by reporting to employment agencies the type of work a person can do efficiently without injury to his physical condition. The cardiac, tuberculous, and lead-poison patients all need change of work; few find it. The majority do as Mr. C., a lead smelter, did. He attended clinic, and stayed away from his work until the acute attack had subsided. He then tried for four days to find other work. As he was not successful, he returned to his old job, and in ten days was back in the clinic with a new attack more serious than the first. Of course, the removal of the hazard is a better way to cure the patient, and has the additional advantage of removing the danger from other workers who are possibly not yet affected. The clinic can do efficient work along these lines if so organized that one of its doctors has time to visit employers and interest them in removing these serious hazards. With the assistance of the Board of Health the Cornell Clinic has this year been able to relieve several cases of this type.

Home Life.—That a knowledge of a man's home is essential at times in directing his treatment is shown in the case of Mr. D.

This man was sadly undernourished. He had been unemployed eight months, but, as he had two grown sons earning good wages, it did not at first occur to us that there were difficulties in his home. A home visit was made subsequently and Mr. D. was found eating dry bread and tea in the kitchen while the rest of the family were enjoying chops and salad in the dining room. His wife explained that if a man was not bringing anything in he surely ought not to expect to eat. This man was too miserable and sick to work. He had an old tuberculous lesion but regained his health to a great extent in the Riverside Hospital.

Another home in which the illness of the man was not appreciated by his wife was that of Mr. B. Mr. B. developed tuberculosis and was sent to Bedford. He gained splendidly, but before he was fit to leave his wife insisted that he return home, threatening to commit the children if he did not do so. After his return, he worked in the special workroom of the Joint Tuberculosis Committee and was carefully watched. His tuberculosis began to increase and in addition he developed appendicitis. The surgeon at Cornell agreed to operate with local anesthesia, so he entered Bellevue. The night before the operation his wife called upon him and filled him with such apprehension that he declined operation and returned home suffering intensely. We can understand Mrs. B.'s distress and can sympathize with her in her anxiety for her husband, but we realize that it is ignorance rather than wilfulness that prompted her to interfere so materially with his welfare. With careful instruction and interested assistance in meeting the many problems her husband's absence gave rise to, she could be stimulated to aid rather than hinder her husband in his recovery.

Conclusions.—I submit these few rather scattered illustrations of fields of activity in which a dispensary has special responsibility. The dispensary has first-hand information on conditions that are hazards to health. It has an opportunity to instruct patients in avoiding such hazards. It has the opportunity of knowing just which factory or workshop is imposing needless hardships on its workers and of what the hardship consists. It knows the long hours of industry, the struggle to maintain life on pay below a minimum living wage, the temptation to take stimulants, and it can judge of the sufferings caused by lockouts and seasonal

unemployment. It frequently learns of failings of private doctors, for the majority of clinic patients have been first to a private doctor but have had to come to a clinic because they were not gaining or their money was gone.

With the possibility of obtaining first-hand information on all these vital questions a dispensary should be an essential force in remedying conditions. It has two unique advantages in rendering this service to the community: First, patients come to a clinic in a state of mind eager to receive instruction. Second, a clinic can be absolutely impersonal; its sole interest is to gain improved conditions for its patients.

To live up to its many opportunities, and fulfill its obligations to the community, a dispensary should be so organized that it can do the following things:

1. Inform the public by various forms of publicity, written and spoken, just what things are injurious to health and how to avoid and remedy them.

2. Visit factories with known hazards, and interest employers in improving conditions so that the health of the workers may be maintained.

3. Stimulate public interest in the importance of recreation and exercise, and devise wholesome forms of both.

4. Educate patients individually in all matters pertaining to diet, bathing, work, exercise and rest.

5. Join with the Board of Health in an active campaign to eliminate industrial poisons.

6. Acquaint itself with the home life, struggles, and ambitions of its patients so that its directions may be individual.

7. Hold clinics at hours when workers are free to attend.

8. Devise means of finding employment for workers crippled in some one way.

9. Educate private doctors by giving them opportunity to know of their successes and failures.

This may sound complex, but in reality it is much that is usually done, only it has not been coordinated. The majority of dispensary patients are suffering from conditions that can be entirely cured. With work on the broad lines outlined above a dispensary could become a vital force in the field of preventive medicine, and justify the object of its existence, viz.: to cure the sick before they require hospital care.

CONSERVATISM IN ROENTGEN DIAGNOSIS OF DISEASE OF THE STOMACH.*

BY WILLIAM H. MEYER, M.D.,

NEW YORK.

DIRECTOR, X-RAY DEPARTMENT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

So much has been written concerning the roentgen diagnosis of gastrointestinal disease, the viewpoint of the various authors so certain, the professed findings so positive as to lead one to wonder whether any means other than the x-ray were really necessary for diagnosis.

In the light of over ten years' experience, it

*Read in part, with lantern slide demonstration, before the Washington Heights Medical Society, Jan. 15, 1918.

seems rather far fetched that, for instance, over 90 per cent. of duodenal ulcers should be positively diagnosed by the roentgen rays. Backed by a proper history, clinical and laboratory findings, these figures may not be greatly exaggerated, but when one considers that pathology in the gall-bladder region or in the right iliac fossa, to say nothing of the rest of the intestinal tract, may produce a symptom complex practically identical with that of a duodenal ulcer, then, from a roentgen standpoint alone would this high percentage receive a serious cut. If it were always possible to identify an ulcer defect or to outrule disease in the cecal region, or to diagnose as high as 85 per cent. of the gall-bladder cases, as is professed by a certain author, then again this high percentage of correct diagnosis of duodenal ulcer might be attained; but granting the necessary time and expense of special attention and technique devoted to the gall-bladder region; even then the anatomical position of the gall-bladder, its pathology, and the chemical composition of biliary calculi preclude the possibility of such a high percentage.

Roentgen evidence of gastrointestinal pathology can be inferred by direct or positive and by indirect findings. By positive evidence is meant the visualization of the exact seat of pathological invasion, by defect in outline, such as irregularity in contour, contraction, niche, or bud. Such defect is conclusive providing that pseudo-defects, local spasm (inherent and reflex), as well as the extrinsic causes simulating true defects can be excluded.

The class of cases offering positive roentgen evidence include the infiltrations, saddle, penetrating, and perforating ulcers, both gastric and duodenal, of course, the defects produced by carcinoma or other new growth, malignant or benign, and syphilis as well as congenital defects and malpositions. This does not mean that each of these has a typical appearance at once distinguished from any other. As a matter of fact, at first glance, a pylorospasm, a syphilitic infiltration of the pylorus, a fibrosis, or a scirrhus carcinoma of the pylorus may give a picture very similar in appearance.

It is not at all rare to have a fair-sized carcinoma of the pylorus with active peristalsis in the balance of the stomach, with evidence of hypersecretion, hyperacidity, and free HCl. I saw three such cases in one week operatively proven; and they occur with sufficient frequency to sound a note of warning, not to bank too strongly upon certain preconceived ideas; it being quite generally accepted that with carcinoma should go diminished or absent peristalsis, as well as diminished secretion and anacidity.

Many a spasm has proven rebellious to anti-spasmodics, often refusing to relax with a second and third reexamination. With syphilis there may be nothing but the history and physical condition of the patient, clinical and laboratory findings to distinguish the case from one of carcinoma. Every case will not give the typical show-plate picture. Thus it will be seen that even some of the so-called positive evidence may be enshrouded in not a little doubt unless viewed from every possible angle.

True defect, pseudo-defect, reflex spasm, extrinsic defects, and adhesions are up to the roentgenologist to differentiate.

A large infiltrating or perforating ulcer, a small carcinoma, or benign tumor, a scirrhus, a fibrosis, or syphilis will occasionally require the combined aid of all diagnostic methods for differential diagnosis, and even then the surgeon may pose as the final judge and refute the preoperative opinion. However, for positive roentgen findings, in the hands of the conservative roentgenologist, I do not hesitate to say that, excepting exploratory laparotomy, no other single diagnostic procedure can compete therewith.

Under positive evidence I have not included certain contributory signs, leaving these for consideration under indirect evidence.

By indirect roentgen evidence of gastric pathology is meant the visualization of disturbances of normal gastric functions. This necessitates the study of the status habitus in relation to the type, filling, tone, size, shape, position, and mobility, peristalsis and motility, i.e. evacuation and abnormal retention.

There is really no cause for a controversy as to the relative value of fluoroscopy or radiography, serial or otherwise; suffice it to say that both should be used, each in its proper sphere. The fluoroscope for the study of the organ in motion, motility and mobility in various postures; the plate for visualizing small defects and finer detail which are frequently overlooked by simple fluoroscopy; besides, the plates have the advantage of permanent record and affording prolonged and more careful study and review.

A careful study of the normal physiological gastric and intestinal function by various observers has given us a reasonable standard of gastrointestinal motility, etc., under varying conditions with various foods.

The grouping together of certain abnormal findings into a so-called symptom complex is indicative of abnormal gastric function, but many of these complices may not only be the expression of intrinsic pathology, but may also be produced by reflex cause. Thus, hypertonus, hyperperistalsis, rapid evacuation, and intestinal hypermotility may indicate a duodenal irritation due to ulcer, but again this same symptom complex may also mean an appendicitis, a gall-bladder disease, a diarrhea and colitis, or other intraabdominal pathology, not to mention hysteria, fright, and the influence of narcotic poisons in producing disturbances of gastric function.

A spastic incisure, a pylorospasm, or spastic duodenal defect may even be added to the above complex and still have the seat of disease in the right iliac fossa or elsewhere, not at all due to gastric or duodenal pathology. On the other hand, a spastic contracture on the greater curvature, a more or less persistent hour-glass with a tender point opposite on the lesser curvature and nothing more, may be indicative of a small ulcer; yet this complex requires a defect or niche for positive roentgen evidence of ulcer.

A six-hour residue may be due to new growth, ulcer, adhesions, spasm, appendicitis, or cholecystitis; yet a residue with hypertonus, hyperperi-

stalsis, and hypermotility, is nine times out of ten (says Carmen) due to duodenal ulcer of the obstructive type. In this connection it is to be remembered that a residue and hypermotility may be indicative of morphinism, though, as a rule, peristalsis is diminished.

Fright, anger, and disgust are also likely to be accompanied by hypomotility and abnormal retention.

A residue with atony, diminished peristalsis, and hypomotility may indicate a pyloric or duodenal obstruction, due to ulcer, adhesions, extrinsic or intrinsic new growth, kink, or paralysis. Delayed motility with six-hour retention and hypotonus may also be due to enteroptotic habitus. A large residue, however, beyond a period of eight or nine hours is quite conclusive of organic obstruction.

Contraction, fixation, pyloric insufficiency, and diminished or absent peristalsis combined are supposedly suggestive of carcinoma. Yet, as has been mentioned before, fibrosis and water-bottle stomach, as well as syphilis, may be responsible for the same complex. In consideration of all this the importance of searching for and demonstrating a defect when true gastric pathology is suspected requires no further discussion.

There are certain more or less characteristic signs that the expert roentgenologist has learned to heed, which often assist in more accurately localizing the type and seat of disease, but indirect roentgen findings are, as a rule, of value only when taken in conjunction with the history, laboratory, and other clinical evidence.

In conclusion the author will state without fear of grave contradiction that in the routine examination of the stomach, in the least number of cases should the x-rays alone be relied upon for a positive diagnosis. On the other hand, we have in the x-ray a visual aid to correct deduction and diagnosis, the value of which cannot be refuted and the use of which in conjunction with other methods should not be denied the patient.

558 WEST 189TH STREET.

Gold Therapy of Tuberculosis.—Lydia De Witt, of Chicago, summarizes in the September number of the *American Review of Tuberculosis* results obtained by treating tuberculous guinea-pigs with the three gold cyanides, AuK(CN)₂, Au(CN), and AuCN. She also details a method developed by her colleague, Cadwell, by which she was able to estimate the minute quantities of gold taken up by the various tissues. About 40 to 50 per cent. of the gold is excreted in the urine and feces in one week after injection. The gold retained in the body is very widely distributed, only the brain containing none, and there is no marked difference between the amounts contained in tuberculous and non-tuberculous tissues. The gold found in liver, spleen and lungs is many times the concentration necessary to prevent the growth of tubercle bacilli in the test tube. Nevertheless under these conditions tubercles grow luxuriantly in such gold-containing organs. De Witt suggests that the gold may be so combined with cell proteins or be in such an inert colloidal form as to be powerless to act on the tubercle bacillus; or the bacilli may be protected by their position in the cell or by their membrane; or the bacilli may acquire a tolerance to gold. It seems very improbable that any gold preparation yet used can be efficient against invasion of the tubercle bacillus. Gold, moreover, promotes a tendency to hemorrhage and frequently hastens the progress of the disease.

Military Medicine.

THE DOCTOR AND DISCIPLINE.

BY FREDERICK CHRISTOPHER, M.D.,

CHICAGO, ILL.

FIRST LIEUTENANT, M.R.C., U.S.A.

Is strict discipline necessary for the medical man? Are doctors as a class particularly poorly amenable to discipline? Does military discipline applied to the physician stifle his free attitude toward medical progress? These questions occupied the mind of the writer with a very personal emphasis during the early part of a recent profitable sojourn at a medical training camp. After recovering from the first icy plunge of changed environment, it is usual for each newcomer to ask himself, "What is this all about? And is it necessary?" Of course he knows that his country is involved in a great war and that he intends to do his part. He has left his practice and his dear ones, and, from a respected man in his community has become a private in a training camp company. He wears no insignia of rank, even though the President himself had indicated on his commission that he was a major, perhaps, or a captain. Instead of his comfortable bed, there is the army cot in a cold barracks crowded with men coughing and snoring. His teeth chattering with the cold, he steals through the grim grey dawn to the latrine to fight among a crowd of others for the privilege of shaving with cold water. His little old Ford at home looms in his thoughts as a palatial limousine as he drags his wet aching feet through miles of snow covered underbrush or seas of mud. His dignity is startled by such commands as, "Hurry, and get those cigarette butts picked up!" or, "It's your turn to black the stove." So it is quite natural for all newcomers at training camps to become introspective. "My part in this war is to alleviate suffering," he says, "to minister to the sick and wounded; can I not do that just as well if I don't know the meaning of 'right by fours' or am not able to lead the setting up exercises?"

The importance of the application of discipline to the men of the line is questioned by no one. Particularly in the present war has this been demonstrated in the many cases where intensive discipline and training have transformed the unreliable into the staunchest and bravest of men. Now the medical man must never forget that he is a component of a branch of the Army. The commanding general looks on the supply train, the engineers, the quartermaster department, the medical and sanitary detachments as supporting arms of his fighting men. Their disposition must be such as to secure that quick coordination which is necessary to win battles. To secure this coordination, the medical commanding officer must have his orders carried out as promptly and efficiently as those of any other branch of the army. To insure hearty and prompt obedience in every detail, he must have thorough discipline, which is the oil of every part of the military machine.

But in the strictly professional field discipline has come to assume an importance that it never did in previous wars. Army medicine on a scientific basis

has become the most useful agent of all times for the development of better methods of prevention and treatment. The larger the number of carefully worked up cases, the more accurate can be the guide for therapy. But the results can never be classified and interpreted unless the handling of the individual cases is as nearly as possible uniform. The Surgeon General is issuing a series of war manuals prepared by the leaders of the profession. These are to serve as the standards of treatment to be used by all until better methods are from time to time demonstrated. So discipline in the purely professional matters themselves has become necessary for the most efficient care of our soldiers.

Is the doctor himself less amenable to discipline than the engineer, the sanitarian, etc.? The foundation of the doctor's philosophy is the search for truth—he shall maintain an attitude of questioning skepticism toward all innovations until their worth has been proved. Every new proposal in medicine quite properly is subjected to the closest scrutiny before it is accepted as a truth. Apparently this research point of view comes into violent conflict with the doctrine of authority. To solve this dilemma the doctor must forget his identity as an individual and remember that he is a part of the great body of the State, whose life, as that of the body in reference to the hand, is essential to his own. Considerations that governed his course as an individual no longer can influence him now that the State is in danger. It becomes evident that to perpetuate those very rights of independent thought which he cherishes, he must subordinate his own opinions and welfare to the welfare of the nation when the latter is imperiled. The body that urgently needs blood is but poorly helped by the heart that has such component individuality that it goes into fibrillary twitching. So, step by step, the reasoning of explanation carries us from the "policing" of the company street to the great principles themselves for the sake of which we have entered the war.

Our ideal medical officer then must be thoroughly versed in discipline. His obedience must be prompt and complete. His commands shall be reasonable and compel action. Only by maintaining the high standard of discipline and efficiency, that it has established, can the Medical Department play its role in the winning of this war. Of the many lessons so ably taught at the medical training camp, the greatest and most valuable seems to be that of discipline.

44 EAST SCHILLER STREET

Shock.—In the *New Orleans Medical and Surgical Journal*, F. W. Parham discusses the literature of shock. He says in part, that the treatment of shock resolves itself into measures intended to raise the blood pressure and restore the animal heat. W. T. Porter (*Boston Medical and Surgical Journal*, May 17, 1917) found a remarkable absence of nervous shock in the midst of the most horrible carnage, so that the psychic factor seemed to play a very small role. In the badly wounded he found the blood pressure a most valuable guide, especially the diastolic. When the

disastolic pressure fell below 50 mm. the condition was very grave and resuscitation was doubtful, but when reaction could be brought about recovery was often rapid. Elevation of the lower limbs and head lowered just below the abdomen was the best position. A special table was devised, which enabled the patient to be kept warm in the proper position. Saline infusion was given for temporary effect and sometimes adrenalin, given in weak solution continuously, was advantageous, but the saline solution was temporary in its effect unless the blood pressure could be raised. Porter speaks highly of respiratory suction, or the thoracic pump. By introducing carbon dioxide into the air breathed the chest was expanded and a powerful traction force exerted on the blood in the liver, drawing it through and establishing reaction in some very bad cases. Cannon (*Boston Medical and Surgical Journal*, June 21, 1917) recognizing that the retention of the blood in the splanchnic area was due to the obstruction in the liver, tried pituitrin diffused over the portal vein, with the intention of producing contraction of the smooth muscle and forcing the blood through. Adrenalin was contraindicated, because it contracted the portal terminal vessels in the liver. It is doubtful if the action of pituitrin can be limited to the portal vessels in the abdomen. Cannon's recommendation would necessitate a certain amount of manipulation in order to deposit the pituitrin, and in any but an abdominal operative case would require a special incision. For this reason then, and also because it would be impossible to confine its action to the portal radicles, it would seem an impracticable procedure. The suggestion of Porter is simple and worthy of trial, because so easy to apply.

Finally, as the alkali reserve is probably reduced in all these cases, the administration of bicarbonate of soda might be tried with advantage. Dawbarn's suggestion of bandaging the limbs is to be employed in conjunction with the respiratory suction. This would have the effect of drawing the blood to the right heart, not only from the vena cava but also from the portal capillaries. There is one danger suggested by Simonds (*Jour. Amer. Med. Assoc.*, September 15, 1917): the suction might, in fat embolism, draw the fatty globules from the lung to the left auricle, and be there sent with fatal effect to the brain. Shock, Parham says, must be considered a disordered condition of the higher nerve centers, due to the centripetally carried impulses of irritation resulting from traumatism, the lowered blood pressure, diminished sensibility, pallor, cold skin, and feeble pulse are to be explained by the diminished volume of blood sent out by the heart owing to its being locked up principally in the splanchnic area. In operative work it may be prevented by local analgesia, whenever it can be applied, and in the traumatisms of accident and war is to be treated by quieting by morphia the irritation of the nervous centers by favoring the flow of blood from the stagnant splanchnic area to the heart and brain and by the application of heat to the surface. The flow of blood to the heart is favored by elevating the lower part of the body and by utilizing the thoracic pump, by

the stimulating effect on respiration of carbon dioxide. Stimulants seem to have no place in the treatment of shock, but the use of saline infusion, of the transfusion of blood with the aid of such agents as pituitrin to raise the blood pressure, may be of temporary benefit. Hypertonic salt solution, with the addition of the calcium salts, will be better retained in the vessels than normal salt solution. Hogan's or Bayliss' addition of acacia to the fluid seems to offer some advantages over the simple physiologic salt solution, but since the escape from the vessels of the blood plasma is a prominent feature in pronounced shock, as shown by the British Research Committee, it can hardly be expected that any of these solutions, even blood itself by transfusion, will remain in the vessels under aggravated conditions of shock unless reaction can first be brought about by other measures, such as suggested by Porter. Such a condition of shock is practically hopeless.

Information Bureau Concerning Nation's Hospitals.—Information concerning the hospitals of the United States has been collated and indexed in the medical section of the Council on National Defense. A central bureau of information concerning the hospital facilities of the country under war conditions is thus provided. The data will be kept up to date from month to month. The bureau has the details of over 1,000 active hospitals and is gathering full data concerning 8,000 other institutions, which include sanatoria, infirmaries, homes, asylums, and dispensaries. What each hospital has contributed in the way of medical men and nurses for war service has been entered on the cards.

American Women Doctors in Foreign Service.—The American Red Cross has sent forty-three women physicians into foreign medical service. These women have not gone as a unit but as individuals and are serving in other countries as well as in France. A list of the names shows that they have come from all parts of the United States.

The Army Nurse Corps.—The strength of the Army Nurse Corps on May 6, 1918, was 9,824, and of this number 3,488 are in service in France or awaiting transportation. These nurses are all women and are all on active duty. On the basis of the present size of the United States Army, the Surgeon General's office computes that at least 24,000 nurses will be needed by January, 1919. If the rate of enrollment since January 1, 1918, continues through the year it will furnish only 21,338 nurses. The Surgeon General's office estimates that the rate of enrollment should be increased in order to meet the additional needs which will result from the large increase in the size of the American Army.

Staten Island Base Hospital Completed.—The United States Base Hospital at Fox Hills, Staten Island, is practically completed, and if necessary injured soldiers can be cared for at the present time. This hospital is said to be the largest on the Atlantic Coast and was built in ninety days, two thousand men having been employed in its construction. The plant comprises seventy-five buildings; among these there are three hospital structures, each accommodating 1,000 patients. Plans have been drawn for more buildings, which will

greatly increase the capacity of the hospital. Major C. A. Simons is in charge of the hospital.

Deaths in Air Camps.—The War Department has issued a report stating that there have been 192 deaths in flying accidents in the aviation schools and camps in this country and at Camp Borden, Toronto, from the date of the establishment of the camps to April 24, 1918. Ellington Field, at Houston, Texas, reports the largest number of deaths, 17, and Camp Taliaferro at Fort Worth, Texas, reports 15 deaths. Most of the remainder of the nineteen camps report only one, two, or three deaths.

The Roosevelt Unit in France.—The forty-sixth annual report of The Roosevelt Hospital, New York, recently made public, states that the Mackay Unit of Roosevelt Hospital in France has recently had under treatment 3,200 patients. Dr. Charles H. Peck, Major M. R. C., is the Director of the unit; Dr. James I. Russell, Major M. R. C., is Chief of the Surgical Division, and Dr. Rolfe F. Floyd, Major M. R. C., is Chief of the Medical Division. The unit includes twenty picked physicians from the visiting and house staff, sixty-five nurses, and high class picked men from other professions and trades, bringing the personnel of the unit up to 150 members.

Germans Destroy Dr. Carrel's Hospital.—The hospital established near the front by Dr. Alexis Carrel of the Rockefeller Institute has been persistently bombed by German aviators and almost demolished. The hospital constantly flew a flag bearing a large red cross and an immense white cross on the lawn served as a further mark of identification. Dr. Carrel will install his hospital in Paris or the suburbs.

Legislation Providing for Vocational Rehabilitation of Disabled Soldiers and Sailors.—A bill providing for the vocational re-education of disabled soldiers and sailors has been introduced in the Senate by Senator Hoke Smith and in the House of Representatives by Representative William J. Sears. The bill includes in its scope only men disabled in military or naval service. Under this bill the Bureau of War Risk Insurance shall have power, and it shall be its duty, to order the person included in this section to follow suitable courses of vocational rehabilitation to be prescribed and provided by the Federal Board for Vocational Education, and every person so ordered to follow a course of vocational rehabilitation while following the same shall receive monthly compensation in a sum equal to the amount of his monthly pay for the last month of his active service. Among the various provisions of the bill is one that all medical and surgical work or other treatment necessary to give functional and mental restoration to disabled persons prior to their discharge from the Army or Navy shall be under the control of the War Department and the Navy Department respectively. There is also pending an amendment to this bill which would include within the benefits of the bill men crippled or disabled in industry. Provision is made for the additional expenditure that this extension of the plan for rehabilitation would entail by which for each dollar of Federal money expended the State shall expend an equal amount for the same purpose.

Deaths in the Service.—MAJOR JAMES CHEW JOHNSON, M. R. C., died of heart disease, following a general physical breakdown caused by overexertion in pathological and research work in a base hospital in France, at his home in New York City, on May 11, aged 48 years. He was a graduate of Johns Hopkins University in 1890.

CAPTAIN HENRY CLEMENT WELKER, M. R. C., of Norristown, Pa., died at Walter Reed Hospital, Washington, D. C., on May 1. He was a member of Base Hospital Unit No. 34 from the Episcopal Hospital, Philadelphia. He was graduated from the medical department of the University of Pennsylvania in the class of 1906. He was a member of the Montgomery County Medical Society, the Medical Society of Pennsylvania, and the American Medical Association.

Dr. D. J. MOONEY, a recent graduate, attached to the house staff of the Post-Graduate Hospital, who went to France with the unit organized by that institution, was killed during the present season, according to a cablegram received at the hospital. No details are reported except that he lost his life during the early days of April.

Jewish Homes Offered to Government.—The trustees of the Montefiore Home and the Hebrew Infant Asylum have outlined plans for extending the work of their institutions to aid the Government in caring for wounded soldiers. The offer of 100 beds made by the Montefiore Home has been accepted by the Government, though as yet it has not been found necessary to use these facilities. An offer has also been made of the newly erected private hospital for the treatment of returning incapacitated officers, which is now under consideration by the Medical Department.

Offer of Long Island Home for Hospital.—Mrs. J. Elliott Langstaff has offered her country seat at Stony Brook, L. I., in the name of the Imperial Order of Daughters of the British Empire in the United States, to the Government for a convalescent hospital for officers.

Preparations for Red Cross Drive.—The organization of the Red Cross for the second war fund drive is completed. The drive, the aim of which is to raise \$100,000,000, will be known as the Second Red Cross War Fund Campaign. It will begin on Monday, May 20, and will continue one week. New York City's allotment is \$25,000,000.

In German Prison Camps.—LIEUT. ABRAHAM STRAUSS, M. R. C., of New York, who has been in France with English troops since last July, was captured by the Germans in the Peronne center on March 21. He is a son of Major Alexander S. Strauss of the National Guard of Rhode Island and a brother of Dr. Israel Strauss of this city.

LIEUTENANT ABRAHAM J. GORDON, M. R. C., of Newark, who went to France several months ago and was reported missing during the early part of April, has been located in a German prison camp.

Work for War Cripples in Pennsylvania.—A recent estimate, made by the Bureau of Employment of the Pennsylvania Department of Labor and Industry, indicates that 42,111 soldiers, sailors, and marines, crippled or permanently disabled in war service, may obtain in that State suitable employment there. A system of card files shows just where these men can be placed.

THE PATHOLOGY OF THE TYPHOID MYELITIDES.

THE typhoid myelitides result from the various reactions and changes arising in the cord due to the specific bacillus or its toxins. Reproduced experimentally, the pathogenic rôle played by the bacillus and its soluble products has now been amply demonstrated and the medullary lesions are those found in other types of infectious myelitis. Macroscopically, the lesions are commonly grouped in foci involving one or several segments of the cord, but in some instances the foci may be scattered in a disorderly way throughout the medullary parenchyma. The lesions consist above all in foci of softening, ordinarily hemorrhagic in character, which may even reach a complete disfluence of the nerve tissue.

The cerebrospinal fluid is abundant, the brain pale, and the pia mater infiltrated by a mild edema. Microscopically, the pia offers a slight infiltration of round cells which invade the white matter in small foci. There is a mild degeneration of the posterior columns, the lesions attaining their greatest intensity in the second lumbar segment and sacral region. What is quite striking, besides the perivascular distribution of the embryonal-cell infiltration, is this same infiltration around the central canal. The gray matter is more involved in the anterior than in the posterior horns. The radicular cells likewise are frequently involved, presenting a marked chromatolysis or undergoing complete disappearance. The posterolateral and posterior cell groups are relatively intact; the neuroglia is in intense proliferation, slightly more evident in the anterior horns. The white matter is more particularly involved in the anterolateral columns; the majority of the cylinder axes are tumefied and their myelin sheaths are fragmented. No bacteria can be discovered. The anterior roots contain a certain number of fibers undergoing degeneration.

The importance of the vascular lesions is striking. The intramedullary vessels are gorged, their walls dilated and thickened, and surrounded by a ring of leucocytes, sometimes forming true pericapillary nodules. The nerve elements are involved, particularly the radicular cells, which are tumefied, their chromatophilous elements being disorganized,

undergoing fragmentation, and finally disappearing. The white matter also degenerates, the myelin sheath disappears from around the axis cylinder, a condition which gives a lacunar aspect to the cord. On the other hand the neuroglia proliferates.

It is hard to estimate to what extent repair can take place, but there are authentic instances of complete clinical recovery. Therefore, it is manifest that the elements of the medullary parenchyma are not death struck from the start and that if the action of the causative agent becomes exhausted a complete functional recovery is, at least, possible. Regeneration of the destroyed nervous elements is, of course, impossible, at least for the cells. A neuroglia sclerosis ensues at the spots where the nervous tissue has disappeared and the myelitis passes to a chronic state.

Long since, Voinot made systematic studies of typhoid cords and constantly found the lesion of the cells in dissolution to be limited to the chromatophilous elements, with migration of the nucleus, liquefaction, and disappearance of the myelin in the nerve tubules, a tumefied axis cylinder, which might be vacuolated or even suppressed in certain areas.

PYROGENIC THERAPY.

THE history of mental disease, from Hippocrates to Freud, is full of empiricism, of groping in the dark, of seeking mental effects in physical causes and in general of casting about for anything which offers the least ray of hope in an admittedly gloomy subject. Many of the old-time therapeutic methods are ludicrous enough, some of them seem impossible, and not a few were absolutely cruel. All were ineffectual. But it would seem that the height of empiricism was reached when the artificial production of fever was used to cure mental disease.

The method sprang out of the observations of the old clinicians who had noted a marked improvement or apparent cure in psychoses following a severe physical illness with pyrexia. Thus a depressed manic might have an attack of pneumonia and, following the crisis, come back to a cheerful and agreeable mental state. Or a paretic might get an infected wound with profuse pus-production; following recovery from which his mental state would clear up remarkably, he might even go on to a remission. From the observation of these phenomena it was but a step to the deduction of a cause and effect relation between them, and the next step was the artificial production of these states as a therapeutic measure in the psychoses.

Some believed that it was the accompanying leucocytosis which had the beneficent effect, so that the production of leucocytosis in one way or another was attempted. From this theory arose the administration of sodium nucleinate in mental disorder, especially in precox and paresis. Other observers held that the physical illness was the essential thing and favored such treatment as the administration of thyroid extract in manic-depressive states in large enough doses to cause the patient to

become ill in bed. The drug would then be withdrawn and the patient recover from both his physical and mental illness.

In a recent issue of the *British Medical Journal** Dr. Auld reports several cases in which he experimented with a bottle of colloidal platinum which was about a year old and which had apparently undergone some change on standing. A small dose of this substance caused a chill and fever much resembling the malarial paroxysm, followed by the subsidence of temperature and improvement in the patient's general condition. Dr. Auld tried this treatment in cases of empyema and pleurisy with good results. It is contraindicated, he said, by high fever, heart disease, high blood pressure, and arteriosclerosis. It is especially adapted to sluggish cases of localized infection with low fever.

Just what causes the alleged favorable effect of such a procedure as the above is a little difficult to say, although theories are not far to seek. Perhaps the intensification of leucocytosis, the rapid mobilization of antibodies, stimulation of protease and lipase, or alteration of the ferment-antiferment titre may all play a part in the process. Dr. Auld suggests that for routine use typhoid vaccine will probably be found to be the best pyrogen. The method is of course only in the experimental stage, but there seems to be no valid reason why it should not be tried in carefully selected cases, provided we heed its sponsor's warning as to contraindications and the avoidance of an overdose or anything like production of "shock."

WHEAT BREAD AND BERIBERI.

IN *Tropical Diseases Bulletin*, Vol. 11, 1918, No. 6, is a résumé by P. W. Bassett Smith of experiments made by Harriette Chick and Margaret Hume concerning the relation of diet to beriberi and polyneuritis avium. The occurrence of cases of beriberi among the military forces in the Dardanelles and Mesopotamia whose diet consisted largely of canned foods and white bread or biscuit made from white flour, directed attention to the examination of these foods as causative agents. The foods, by the heat sterilization they receive, are well known to be deprived of their anti-beriberi constituent. Chick and Hume, therefore, by a number of well-considered experiments, determined the nutritive properties of cereals generally, and wheat in particular. Two methods of experimentation are applicable—preventive and curative. The former was the most satisfactory method for determining the vitamine content of the foodstuffs, since it gives more regular results, but long and careful research is required so that curative experiments were also carried out. It was proved that in both the rice and wheat grain the anti-neuritic vitamine is concentrated mainly in the germ or embryo, a small amount only being present in the bran, all of which is absent in white

flour. Therefore, the importance is evident of including the germ in the flour from which the bread is made, especially when the diet consists largely of canned foods. It was found that "the daily ration of wheat germ required to be added to a diet of polished rice to prevent the onset of polyneuritis is the amount which, administered by the mouth, will cure a pigeon acutely ill with polyneuritis brought on by an exclusive diet of polished rice." It was also determined that the addition of wheat germ to a diet of polished rice sufficient to prevent polyneuritis also maintained the weight and general health of the birds. Rations in excess of this led to an increase of body weight and in the general well-being and vitality of the birds, whereas extracts of the rice, bran, or yeast, although sufficient to prevent polyneuritis, did not maintain weight.

A further series of experiments was made to determine the influence of exposure to high temperatures on the vitamins in the different foodstuffs, the deficiency of which causes polyneuritis in birds and beriberi in man. Although many observations on this point have been made, no accurate readings have been systematically taken before of the real temperature reached and maintained in the interior of the substances heated. Chick and Hume describe in detail the method employed, and from the tests curves were constructed from which accurate estimates could be made of the temperatures actually experienced by the materials exposed. From these they drew the following conclusions: (1) Exposure of wheat embryo to a temperature of about 100° C. for two hours resulted in no significant loss in anti-neuritic vitamine. If, therefore, the embryo is included in the flour from which the bread or biscuit is made, it can be relied upon to retain its anti-neuritic properties after baking. (2) At temperatures of about 120° C., however, there was a swift destruction of anti-neuritic properties. When soluble yeast extracts containing about 35 per cent. of solids were similarly treated, slight loss of vitamine was evident, after one hour's exposure to 100° C., relatively rather more than with wheat embryo; but at 120° C. destruction of the vitamine was rapid.
